DESCRIPTIONModified Steroid Hormones For Gene Therapy
And Methods For Their UseStatement of Rights

The invention described herein was developed in part with funds provided by the National Institutes of Health, Grant Number HD07857. The Government has certain rights.

5 Related Applications

This application is related to copending U.S. Application Serial No. 08/479,913, O'Malley et al., filed June 7, 1995, entitled "Modified Steroid Hormones for Gene Therapy and Methods for Their Use," which is a
10 continuation-in-part of copending U.S. Application Serial No. 07/939,246, Vegeto, et al., filed September 2, 1992, entitled "Mutated Steroid Hormone Receptors, Methods for Their Use and Molecular Switch for Gene Therapy," the whole of which (including drawings) are both hereby
15 incorporated by reference. In addition, this application is related to U.S. Patent No. 5,364,791, Vegeto, et al., issued November 15, 1994, entitled "Progesterone Receptor Having C-Terminal Hormone Binding Domain Truncations," and PCT/US93/04399 the whole of which (including drawings) are
20 both hereby incorporated by reference.

Introduction

This invention relates to gene therapy, whereby modified steroid receptors regulate the expression of genes within tissue. In particular, the modified steroid
25 receptors contain a DNA binding domain, one or more transregulatory domains, and a ligand binding domain and are capable of binding a non-natural ligand.

Background of the Invention

The following description of the background of the invention is provided to aid in the understanding of the invention but is not admitted to describe or constitute prior art to the invention.

Intracellular receptors are a superfamily of related proteins that mediate the nuclear effects of steroid hormones, thyroid hormone and vitamins A and D (Evans, *Science* 240:889-895 (1988)). The cellular presence of a specific intracellular receptor defines that cell as a target for the cognate hormone. The mechanisms of action of the intracellular receptors are related in that they remain latent in the cytoplasm or nuclei of target cells until exposed to a specific ligand (Beato, *Cell* 56:335-344 (1989); O'Malley, et al., *Biol. Reprod.* 46:163-167 (1992)). Interaction with hormone then induces a cascade of molecular events that ultimately lead to the specific association of the activated receptor with other proteins or regulatory elements of target genes. The resulting positive or negative effects on regulation of gene transcription are determined by the cell-type and promoter-context of the target gene.

In the case of steroid hormones and steroid receptors, such complexes are responsible for the regulation of complex cellular events, including activation or repression of gene transcription. For example, the ovarian hormones, estrogen and progesterone, are responsible, in part, for the regulation of the complex cellular events associated with differentiation, growth and functioning of female reproductive tissues. Likewise, testosterone is responsible for the regulation of complex cellular events associated with differentiation growth and function of male reproductive tissues.

In addition, these hormones play important roles in development and progression of malignancies of the reproductive endocrine system. The reproductive steroids estrogen, testosterone, and progesterone are implicated in

a variety of hormone-dependent cancers of the breast (Sunderland, et al., *J. Clin. Oncol.* 9:1283-1297 (1991)), ovary (Rao, et al., *Endocr. Rev.* 12:14-26 (1991)), endometrium (Dreicer, et al., *Cancer Investigation* 10:27-41, 5 (1992)), and possibly prostate (Daneshgari, et al., *Cancer* 71:1089-1097 (1993)). In addition, the onset of postmenopausal osteoporosis is related to a decrease in production of estrogen (Barzel, *Am. J. Med.* 85:847-850 (1988)).

10 In addition, corticosteroids are potent and well-documented mediators of inflammation and immunity. They exert profound effects on the production and release of numerous humoral factors and the distribution and proliferation of various cellular components associated with the
15 immune and inflammatory responses. For example, steroids are able to inhibit the production and release of cytokines (IL-1, IL-2, IL-3, IL-6, IL-8, TNF- α , IFN- γ), chemical mediators (eicosinoids, histamine), and enzymes (MMPs) into tissues, and directly prohibit the activation
20 of macrophages and endothelial cells. Due to the global down-regulation of these physiological events, corticosteroids have a net effect of suppressing the inflammatory response and have therefore been used extensively to treat a variety of immunological and inflammatory disorders
25 (rheumatoid arthritis, psoriasis, asthma, allergic rhinitis, etc.).

Besides the therapeutic benefits, however, there are some severe toxic side effects associated with steroid therapy. These include peptic ulcers, muscle atrophy,
30 hypertension, osteoporosis, headaches, etc. Such side effects have hindered the utilization of steroids as therapeutic agents.

In general, the biological activity of steroid hormones is mediated directly by a hormone and tissue-specific intracellular receptor. Ligands are distributed
35 through the body by the hemo-lymphatic system. The hormone freely diffuses across all membranes but manifests

its biological activity only in those cells containing the tissue-specific intracellular receptor.

In the absence of ligand, the inactive steroid hormone receptors such as the glucocorticoid ("GR"), mineral corticoid ("MR"), androgen ("AR") progesterone ("PR") and estrogen ("ER") receptors are sequestered in a large complex consisting of the receptor, heat-shock proteins ("hsp") 90, hsp70 and hsp56 and other proteins as well (Smith, et al., *Mol. Endo.* 7:4-11 (1993)). The cellular localization of the physiologically inactive form of the oligomeric complex has been shown to be either cytoplasmic or nuclear (Picard, et al., *Cell Regul.* 1:291-299 (1992); Simmons, et al., *J. Biol. Chem.* 265:20123-20130 (1990)).

Upon binding its agonist or antagonist ligand, the receptor changes conformation and dissociates from the inhibitory heteromeric complex (Allan, et al., *J. Biol. Chem.* 267:19513-19520 (1992); Allan, et al., *P.N.A.S.* 89:11750-11754 (1992)). In the case of GR and other related systems such as AR, MR, and PR, hormone binding elicits a dissociation of heat shock and other proteins and the release of a monomeric receptor from the complex (O'Malley, et al., *Biol. Reprod.* 46:163-167 (1992)). Studies from genetic analysis and *in vitro* protease digestion experiments show that conformational changes in receptor structure induced by agonists are similar but distinct from those induced by antagonists (Allan, et al., *J. Biol. Chem.* 267:19513-19520 (1992); Allan, et al., *P.N.A.S.* 89:11750-11754 (1992); Vegeto, et al., *Cell* 69:703-713 (1992)). However, both conformations are incompatible with hsp-binding.

Following the conformation changes in receptor structure, the receptors are capable of interacting with DNA. Studies suggest that the DNA binding form of the receptor is a dimer. In the case of GR homodimers (Tsai, et al., *Cell* 55:361-369 (1988)), this allows the receptor to bind to specific DNA sites in the regulatory region of

target gene promoters (Beato, *Cell* 56:335-344 (1989)). These short nucleotide sketches are arranged as palindromic, inverted or repeated repeats (*Id.*). Specificity is determined by the sequence and the spacing
5 of the repeated sequences (Tsai and O'Malley, *Ann. Rev. Biochem.* 63:451-486 (1994)). Following binding of the receptor to DNA, the hormone is responsible for mediating a second function that allows the receptor to interact specifically with the transcription apparatus. Such
10 interaction could either provide positive or negative regulation of gene expression, i.e., steroid receptors are ligand-binding transcription factors, capable of not only activating but also repressing the expression of specific genes. Studies have shown, however, that repression does
15 not require DNA binding.

For instance, when bound to their intracellular receptors, corticosteroids can affect the transcription of a variety of genes whose products play key roles in the establishment and progression of an inflamed situation.
20 Such genes include those encoding for cytokines, chemical mediators and enzymes. Transcription of these genes can be repressed or activated depending on the transcription factors and/or regulatory sequences controlling the expression of the gene. Presently there are numerous
25 reports documenting the effect of glucocorticoid on the expression of various genes at the transcriptional level.

In particular, the glucocorticoid receptor is a member of a family of ligand-dependent transcription factors capable of both positive and negative regulation
30 of gene expression (Beato, *FASEB J.* 5:2044-2051 (1991); Pfahl, *Endocr. Rev.* 14:651-658, (1993); Schule, et al., *Trends Genet.* 7:377-381 (1991)). In its inactivated form, the GR is part of a large heteromeric complex which includes hsp90 as well as other proteins (Denis, et al.,
35 *J. Biol. Chem.* 262:11803-11806 (1987); Howard, et al., *J. Biol. Chem.* 263:3474-3481 (1988); Mendel, et al., *J. Biol. Chem.* 261:3758-3763 (1986); Rexin, et al., *J. Biol. Chem.*

267:9619-9621 (1992); Sanchez, et al., *J. Biol. Chem.* 260:12398-12401 (1985)), and hsp56 (Lebea, et al., *J. Biol. Chem.* 267:4281-4284 (1992); Pratt, *J. Steroid Biochem. Mol. Biol.* 46:269-279 (1993); Sanchez, *J. Biol.*
5 *Chem.* 265:22067-22070 (1990); Yem, *J. Biol. Chem.* 267:2868-2871, (1992)). Binding of agonist stimulates receptor activation, dissociation from hsp90 and the other proteins (Denis, et al., *Nature* 333:686-688 (1988); Sanchez, et al., *J. Biol. Chem.* 262:6986-6991 (1987)), and
10 nuclear translocation, prerequisites for both trans-activation and transrepression.

Cloning of several members of the steroid receptor superfamily has facilitated the reconstitution of hormone-dependent transcription in heterologous cell systems and
15 facilitated delineation of the GR activation and repression mechanisms. Subsequently, *in vivo* and *in vitro* studies with mutant and chimeric receptors have demonstrated that steroid hormone receptors are modular proteins organized into structurally and functionally
20 defined domains. Deletion mutants of the GR have determined that the transactivation domain is located at the N-terminal amino acid sequence positioned between amino acids 272 and 400 (Jonat, et al., *Cell* 62:1189-1204 (1990)). A well defined 66 amino acid DNA binding domain
25 ("DBD") has been identified and studied in detail, using both genetic and biochemical approaches (Lucibello, et al., *EMBO J.* 9:2827-2834 (1990)). The ligand or hormone binding domain ("LBD"), located in the carboxyl-terminal portion of the receptor, consists of about 300 amino acids
30 (Kerppola, et al., *Mol. Cell. Biol.* 13:3782-3791 (1993)). The LBD has not been amenable to detailed site-directed mutagenesis, since this domain appears to fold into a complex tertiary structure, creating a specific hydrophobic pocket which surrounds the effector ligand
35 when bound. This feature creates difficulty in distinguishing among amino acid residues that affect the overall structure of the LBD domain from those involved in a

direct contact with the ligand. The LBD also contains sequences responsible for receptor dimerization, nuclear localization, hsp interactions and transactivation sequences of the receptor (Fuller, et al, *FASEB J.* 5:3092-3099 (1991)).

The mechanism of gene activation is generally better understood than that of repression. For transactivation, a ligand-induced conformational change, comparable to that inferred to be necessary for activation of the progesterone (Allan, et al., *Proc. Natl. Acad. Sci. USA* 89:11750-11754 (1992)) and estrogen (Beekman, et al., *Mol. Endocrinol.* 7:1266-1274 (1993)) receptors, is required for efficient activation of the transcription activating function of the receptor (Hollenberg and Evans, *Cell* 55:899-906 (1988); Webster, et al., *Cell* 54:199-207, (1988)). Furthermore, the conformational change is required for interaction of the receptor with other components of the transcription apparatus. Transactivation is mediated by a receptor dimer bound to a glucocorticoid response element ("GRE"). Such transactivation occurs exclusively by homodimerization. This is mainly achieved by a region in the second zinc finger of the receptor known as the D-loop (Umesono, et al., *Cell* 57:1139-1146 (1989); Dahlman-Wright, et al., *J. Biol. Chem.* 266:3107-3112 (1991)). The resulting homodimers then bind to the palindromic GRE to initiate the transcriptional activation process (Evans, *Science* 240:889-895 (1988); Cato, et al., *J. Steroid Biochem. Mol. Biol.* 43:63-68 (1992)).

Transrepression, on the other hand, appears to be mediated by the monomeric form of the receptor through interactions with other transcriptional factors, including AP-1 and NF κ -B, preventing them from carrying out their function as transcriptional activators (Hoeck, et al., *EMBO J.* 13:4087-4095 (1994)). Studies also show transrepression by the dimeric form of the receptor. In the case of the monomeric pathway, studies suggest that AP-1

prevents hormone-dependent activation of GR-regulated promoters through a mutually inactive complex formed either by a direct protein-protein interaction of the receptor and AP-1 or through a third partner (Miner, et al., *Cell Growth Differ.* 2:525-530 (1991); Pfahl, *Endocrine Rev.* 14:651-658 (1993)). Such transrepression of AP-1 and NF κ -B mediated by the monomeric form of the receptor depends on the presence of the DNA binding domain. It does not depend on the ability of the receptor to bind DNA. In the case of the dimeric form of the receptor, several studies suggest mechanisms for such GR-mediated transrepression include GR binding to a sequence overlapping a *cis*-acting element for another *trans*-acting factor, thereby displacing it from, or preventing its binding to, its cognate element (Akerblom, et al., *Science* 241:350-353 (1988); Drouin, et al., *Mol. Cell. Biol.* 9:5305-5314 (1989); Oro, et al., *Cell* 55:1109-1114, (1988); Stromstedt, et al., *Mol. Cell. Biol.* 11:3379-3383, (1991)).

As noted above, GR-mediated transrepression attributed to direct or indirect interaction of the GR with other *trans*-acting factors, results in inhibition of their activity and/or ability to bind to DNA (Celada, et al., *J. Exp. Med.* 177:691-698 (1993); Diamond, et al., *Science* 249:1266-1272 (1990); Gauthier, et al., *Embo J.* 12:5089-5096 (1993); Jonat, et al., *Cell* 62:1189-1204 (1990); Kutoh, et al., *Mol. Cell Biol.* 12:4955-4969 (1992); Lucibello, et al., *Embo J.* 9:2827-2834 (1990); Ray, et al., *Proc. Natl. Acad. Sci. USA* 91:752-756 (1994); Schule, et al., *Cell.* 62:1217-1226 (1990); Tverberg, et al., *J. Biol. Chem.* 267:17567-17573 (1992); Yang-Yen, et al., *Cell* 62:1205-1215 (1990); Lucibello, et al., *EMBO J.* 9:2827-2834 (1990)). These models require ligand binding to stimulate receptor activation, dissociation from hsp90, and nuclear translocation. It is not clear whether these mechanisms are dependent on the same ligand-induced conformational change needed for transactivation. However,

a transactivation-defective mutant represses the AP-1 dependent promoter suggesting that the transactivation function of the receptor is not required for the repression of AP-1 activity (Yang-Yen, et al., *Cell* 5 62:1205-1215 (1990)). Furthermore, similar studies also suggest that the transactivation function of the receptor is not required for the repression of NF κ -B activity.

In attempts to decipher the transrepression mechanism, studies have reviewed the role of the bound 10 ligand in GR-mediated repression of AP-1-responsive genes containing a tetradecanoyl phorbol acetate ("TPA") response element. Repression of these genes has been proposed to be the result of the direct interaction of the GR with c-Jun (Diamond, et al., *Science* 249:1266-1272 15 (1990); Lucibello, et al., *EMBO J.* 9:2827-2834 (1990); Schule, et al., *Cell* 62:1217-1226 (1990); Touray, et al., *Oncogene* 6:1227-1234 (1991); Yang-Yen, et al., *Cell* 62:1205-1215 (1990)) or c-Fos (Kerppola, et al., *Mol. Cell. Biol.* 13:3782-3791 (1992)) which are components of 20 the AP-1 transcription complex. The GR DNA-binding domain is necessary for this interaction, since most mutations in this domain result in the loss of repressor activity *in vivo* (Diamond et al., *Science* 249:1266-1272 (1990); Jonat et al., *Cell* 62:1189-1204 (1990); Lucibello et al., *EMBO J.* 9:2827-2834 (1990); Schule et al., *Cell* 62:1217-1226 25 (1990); Yang-Yen et al., *Cell* 62:1205-1215 (1990)).

The DNA-binding domain is also necessary for inhibition of *in vitro* transcription from the collagenase promoter and inhibition of Jun-Fos heterodimer binding to 30 the collagenase TPA response element (Mordacq et al., *Genes Dev.* 3:760-769 (1989)). However, deletion or truncation of the ligand-binding domain also results in a significant loss of repressor activity (Jonat et al., *Cell* 62:1189-1204 (1990); Schule et al., *Cell* 62:1217-1226 35 (1990); Yang-Yen et al., *Cell* 62:1205-1215 (1990)), suggesting that the ligand-binding domain may contribute to, or modulate, the inhibition of AP-1 activity.

Further studies examining the role of the ligand in GR-mediated transrepression of the collagenase promoter found efficient receptor-mediated transrepression with ligand-free mutant GR in which the first cysteine residue of the proximal zinc finger was replaced with tyrosine (Liu et al., *Mol. Cell. Bio.* 15:1005-1013 (1995)). Such studies suggest that neither retention of the ligand nor direct binding of the receptor to DNA is required, i.e., that transrepression of AP-1 activity by GR is ligand independent.

The expression of most mammalian genes is intricately regulated *in vivo* in response to a wide range of stimuli, including physical (pressure, temperature, light), electrical (e.g. motor and sensory neuron signal transmission) as well as biochemical (ions, nucleotides, neurotransmitters, steroids and peptides) in nature. While the mechanism of transcriptional regulation of gene expression has been extensively studied (McKnight, *Genes Dev.* 10:367-381 (1996)), progress on achieving target gene regulation in mammalian cells, without interfering with endogenous gene expression, has been limited. Currently, most strategies for target gene activation or repression are performed in a constitutive manner. Such uncontrolled regulation of gene expression is not ideal physiologically, and can even be deleterious to cell growth and differentiation. In contrast, use of the yeast GAL4 DNA binding domain in this invention does not interfere with endogenous genes since that chimeric regulator will only recognize target gene constructs containing the GAL4 binding sequence.

Several inducible systems have been employed for controlling target gene expression. These inducible agents include heavy metal ions (Mayo et al., *Cell* 29:99-108 (1982)), heat shock (Nover et al. *CRC Press* 167-220 (1991)), isopropyl β -D-thiogalactoside (β -gal) (Baim et al. *Proc. Natl. Acad. Sci.* 88:5072-5076 (1991)), and steroid hormones such as estrogen (Brasemann et al. *Proc.*

Natl. Acad. Sci. 90:1657-1661 (1993)) and glucocorticoids (Lee et al. *Nature* 294:228-232 (1981)). However, many of these inducers are either toxic to mammalian cells or interfere with endogenous gene expression (Figge et al. 5 *Cell* 52:713-722 (1988)).

Utilizing a bacterial tetracycline-responsive operon element, Gossen et al. developed a model for controlling gene expression with a tetracycline-controlled trans-activator (tTA and rtTA) (Gossen et al. *Proc. Natl. Acad. Sci.* 89:5547-5551 (1992); Gossen et al. *Science* 268:1766-1769 (1995)). No et al. recently reported a three-component system consisting of a chimeric GAL4-VP16-ecdysone receptor, its partner retinoid X receptor (RXR), and a target gene. They demonstrated its application in 15 activating reporter gene expression in an ecdysone-dependent manner (No et al. *Proc. Natl. Acad. Sci.* 93:3346-3351 (1996)). The invention described herein has advantages over the No and Gossen models, as the chimeric regulator recognizes only the target gene constructs and 20 not endogenous genes, and the system is only activated in the presence of an exogenous compound, but not in the presence of any endogenous molecules.

Summary of the Invention

Construction of novel modified steroid hormone 25 receptors which regulate the expression of nucleic acid sequences is described herein, and surprisingly these modifications allow control of the transactivation and transrepressing functions of the modified steroid hormone receptor. Such modifications unexpectedly allow the 30 receptors to bind various ligands whose structures differ dramatically from the naturally-occurring ligands (for example, non-natural ligands, anti-hormones and non-native ligands) and thereby provide a substantial improvement over prior attempts to control or regulate target gene 35 expression.

These modifications are generated in the ligand binding domain of the GR and eliminate the ability of the GR to bind its natural ligand. These modified steroid receptors exhibit normal transactivation and transrepression activity; however, stimulation of such activity occurs via activation by a non-natural and exogenously or endogenously applied ligand. Modifications are also generated in the ligand binding domain of the PR and eliminate the ability of PR to bind its natural ligand.

10 Replacement of the GR binding domain with the modified PR binding domain allows the stimulation of GR responsive gene expression via non-natural ligands.

Other modifications to the GR ligand binding domain in conjunction with modifications to the DNA binding domain of GR eliminate the ability of steroid hormones to initiate transactivation by its natural ligand. Instead, such modifications allow the modified receptor to bind non-natural ligands and stimulate the transrepression of gene expression but not transactivation. Likewise, using

20 the same ligand binding domain modification in conjunction with modifications to the transregulatory domain allows the modified receptor to bind non-natural ligands and stimulate transactivation but not transrepression of gene expression.

25 Other modifications remove the ligand binding domain completely to create a constitutively active steroid receptor. Such modifications cause continual transactivation and transrepression effects on the regulation of gene transcription. In addition, modifications that selectively eliminate either transactivation or transrepression functions are incorporated into the constitutively active steroid receptor thereby constitutively transrepressing or transactivating gene expression. Furthermore, other modifications use a ligand binding domain which recognizes its

30 natural ligand or if modified recognizes a non-natural ligand, but is fused with a DNA binding domain and transregulatory domains not associated normally with the ligand

35

binding domain. Such a construct is capable of regulating the expression of a gene not normally associated with the ligand binding domain in a wild type receptor protein.

These modified receptors can be expressed by specially designing DNA expression vectors to control the level of expression of recombinant gene products. The steroid receptor family of gene regulatory proteins is an ideal set of such molecules. These proteins are ligand activated transcription factors whose ligands can range from steroids to retinoids, fatty acids, vitamins, thyroid hormones and other presently unidentified small molecules. These compounds bind to receptors and either activate or repress transcription.

These receptors are modified to allow them to bind various ligands whose structure is either naturally occurring or differs from naturally occurring ligands. By screening receptor mutants, receptors can be selected that respond to ligands which do not activate the host cell endogenous receptor. Thus, regulation of a desired transgene can be achieved using a ligand which binds to and regulates a customized receptor. This occurs only with cells that have incorporated and express the modified receptor.

Taking advantage of the abilities of the modified steroid hormone receptor to effect regulation of gene expression, these gene constructs can be used as therapeutic gene medicines, for gene replacement, and in gene therapy. These modified receptors are useful in gene therapy where the level of expression of a gene, whether transactivation or repression, is required to be controlled. The number of diseases associated with inappropriate production or responses to hormonal stimuli highlights the medical and biological importance of these constructs.

The properties of the modified steroid hormone receptors allow most or all of the deleterious effects of steroids to be avoided while generally maintaining their

therapeutic benefits. In particular, administration of steroids typically causes toxicity problems. The deleterious effects of steroids can be attributed to the *in vivo* transactivation or transrepression of certain genes.

5 These toxic effects may well be the result of both transactivation and transrepression, or be primarily attributable to one of them. The present invention features the use of modified GR molecules as gene medicines for the replacement of steroid therapy. These

10 synthetic receptors retain functions similar to those of the endogenous receptors, but by responding to alternative ligands, eliminate some of the toxic side effects attributable to currently used steroid therapy.

This ability of the GR constructs to avoid steroid

15 toxicity but still exhibit therapeutic effects allows the constructs to be used for treating numerous diseases, including arthritis, asthma, senile dementia or Parkinson's disease. Furthermore, the constructs can be used for preventing or treating diseases in which inappropriate production or responses to hormonal stimuli

20 exists, e.g., hormone-dependent cancers of the breast, ovary, endometrium, prostate, and post-menopausal osteoporosis. The constructs also can be used in conjunction with co-transfected expression vectors so as to operate as

25 a gene switch. For detailed description of gene switch, see, U.S. Application Serial No. 07/939,246, Vegeto et al., and U.S. Patent No. 5,364,791, Vegeto et al., the whole of which (including drawings) are both hereby incorporated by reference.

30 In addition, the constructs above can be used for gene replacement therapy in humans and for creating transgenic animal models used for studying human diseases. The transgenic models can be used as well for assessing and exploring novel therapeutic avenues to treat effects

35 of chemical and physical carcinogens and tumor promoters. The above constructs can also be used for distinguishing steroid hormone receptor antagonists and steroid hormone

receptor agonists. Such recognition of antagonist or agonist activity can be performed using cells transformed with the above constructs. Thus, in view of the above, various aspects of the invention will now be described.

5 In a first aspect, the present invention features a modified glucocorticoid receptor fusion protein. The fusion protein receptor contains a GR with its ligand-binding domain replaced with a mutated PR ligand-binding domain. This fusion protein is capable of being activated
10 by the binding of a non-natural ligand, but not by natural or synthetic glucocorticoid or other natural or synthetic steroids. The fusion protein includes a glucocorticoid receptor region which comprises a DNA binding domain and one or more transregulatory domains. The transregulatory
15 domains are capable of transactivating or transrepressing glucocorticoid responsive gene expression.

In addition to the glucocorticoid receptor region, the fusion protein also includes a mutated progesterone ligand binding region which is capable of binding a non-
20 natural ligand. The mutated ligand binding region is preferably mutated by deletion of about 16 to 42 carboxyl terminal amino acids of a progesterone receptor ligand binding domain. The mutated progesterone receptor ligand binding region preferably comprises, consists essentially
25 of, or consists of about amino acids 640 through 891 of a progesterone receptor. Other preferred embodiments comprise, consist essentially of, or consist of amino acids 640-917, amino acids 640-920 or amino acids 640-914. One skilled in the art will recognize that various mutations
30 can be created to achieve the desired function.

The term "fusion protein" as used herein refers to a protein which is composed of two or more proteins (or fragments thereof) where each protein occurs separately in nature. The combination can be between complete amino
35 acid sequences of the protein as found in nature, or fragments thereof. In the case of the glucocorticoid-progesterone fusion protein receptor, the fusion protein

is preferably composed of portions of the glucocorticoid receptor and the progesterone receptor. This combination can include the complete amino acid sequence of each protein or fragments thereof. For example, the
5 glucocorticoid-progesterone fusion protein may include the ligand binding domain of progesterone and the DNA binding domain and transregulatory domains of the glucocorticoid receptor. This is only an example and not meant to be limiting.

10 The term "non-natural ligand" as used herein refers to compounds which can normally bind to the ligand binding domain of a receptor, but are not the endogenous ligand. "Endogenous" as used herein refers to a compound originating internally within mammalian cells. The
15 receptor is not exposed to the ligand unless it is exogenously supplied. "Exogenous" as used herein refers to a compound originating from external sources and not normally present within mammalian cells. This also includes ligands or compounds which are not normally found
20 in animals or humans. Non-natural also includes ligands which are not naturally found in the specific organism (man or animal) in which gene therapy is contemplated. These ligands activate receptors by binding to the modified ligand binding domain. Activation can occur
25 through a specific ligand-receptor interaction whether it is through direct binding or through association in some form with the receptor.

"Natural ligand" as used here refers to compounds which normally bind to the ligand binding domain of a
30 receptor and are endogenous. The receptor in this case is exposed to the ligand endogenously. Natural ligands include steroids, retinoids, fatty acids, vitamins, thyroid hormones, as well as synthetic variations of the above. This is meant to be only an example and non-
35 limiting.

The term "ligand" as referred to herein means any compound which activates the receptor, usually by

interaction with the ligand binding domain of the receptor. Ligand includes a molecule or an assemblage of molecules capable of specifically binding to a modified receptor. The term "specifically binding" means that a
5 labeled ligand bound to the receptor can be completely displaced from the receptor by the addition of unlabeled ligand, as is known in the art.

Examples of non-natural ligands and non-native ligands may be found in PCT Publication PCT/US96/04324,
10 the whole of which (including drawings) is hereby incorporated by reference.

The term "binding" or "bound" as used herein refers to the association, attaching, connecting, or linking through covalent or non-covalent means, of a ligand,
15 whether non-natural or natural, with a corresponding receptor. The ligand and receptor interact at complementary and specific within sites on a given structure. Binding includes, but is not limited to, components which associate by electrostatic binding, hydrophobic binding,
20 hydrogen binding, intercalation or forming helical structures with specific sites on nucleic acid molecules.

The term "glucocorticoid receptor" refers to a steroid hormone receptor which responds to a glucocorticoid ligand. The glucocorticoid receptor is part of the
25 steroid hormone receptor superfamily which are known steroid receptors whose primary sequence suggests that they are related to each other. Representative examples of such receptors include the estrogen, progesterone, Vitamin D, chicken ovalbumin upstream promoter trans-
30 factor, ecdysone, Nurrr-1 and orphan receptors, glucocorticoid- α , glucocorticoid- β , mineralocorticoid, androgen, thyroid hormone, retinoic acid, and retinoid X. These receptors are composed of DNA binding domains, ligand binding domains, as well as transregulatory domains.

35 The glucocorticoid receptor is a ligand-dependent transcription factor capable of both positive and negative regulation of gene expression. Interaction of the

receptor with a ligand induces a cascade of molecular events that ultimately lead to the specific association of the activated receptor with regulatory elements of target genes. In an inactive form such receptors form a large
5 complex comprising the receptor, heat shock proteins and other proteins.

The term "glucocorticoid receptor region" refers to a fragment or part of the complete glucocorticoid receptor as defined above. A glucocorticoid receptor region may
10 retain complete or partial activity of the natural receptor protein. For example, a glucocorticoid receptor region might contain only the DNA binding domain and the transregulatory domains and not the ligand binding domain, or vice versa. This is only an example and not meant to
15 be limiting.

The term "ligand binding domain" or "ligand binding region" as used herein refers to that portion of a steroid hormone receptor protein which binds the appropriate hormone or ligand and induces a cascade of molecular
20 events that ultimately leads to the specific association of the activated receptor with regulatory elements of target genes. This includes, but is not limited to, the positive or negative effects on regulation of gene transcription. Binding of ligand to the ligand binding domain
25 induces a conformation change in the receptor structure. The conformational change includes the dissociation of heat shock proteins and the release of a monomeric receptor from the receptor complex, as well as a different tertiary or 3-dimensional structure. The conformational
30 change that occurs is specific for the steroid receptor and ligand that binds to the ligand binding domain.

For example, for glucocorticoid receptors, the conformation change that occurs when glucocorticoid hormone binds allows homodimerization, i.e., dimerization
35 between two identical GR molecules. However, heterodimerization can occur with other steroid receptors, i.e., dimerization with two molecules such as GR and ER. Such

dimerization allows the receptor to bind with DNA or induce the regulatory effect by binding other transcription factors.

The term "DNA binding domain" as used herein refers to that part of the steroid hormone receptor protein which binds specific DNA sequence in the regulatory regions of target genes. This domain is capable of binding short nucleotide stretches arranged as palindromic, inverted or repeated repeats. Such binding, will activate gene expression depending on the specific ligand and the conformational changes due to such ligand binding. For repression, DNA binding is not needed.

The term "transregulatory domain" as used herein refers to those portions of the steroid hormone receptor protein which are capable of transactivating or transrepressing gene expression. This would include different regions of the receptor responsible for either repression or activation, or the regions of the receptor responsible for both repression and activation. Such regions are spatially distinct. The above is only an example and meant to be non-limiting. For transrepression, this domain under one mechanism is involved with dimerization which in turn causes a protein/protein interaction to prevent or repress gene expression. Such regulation occurs when the receptor is activated by the ligand binding to the ligand binding domain. The conformational change of the receptor is capable of forming a dimer with a discrete portion of the transregulatory domain to repress gene expression. In addition, repression can occur through a monomeric form of the receptor, however, DNA binding is not necessary (see below).

The terms "transactivation," "transactivate," or "transactivating" refer to a positive effect on the regulation of gene transcription due to the interaction of a hormone or ligand with a receptor causing the cascade of molecular events that ultimately lead to the specific association of the activated receptor with the regulatory

elements of the target genes. Transactivation can occur from the interaction of non-natural as well as natural ligands. Agonist compounds which interact with steroid hormone receptors to promote transcriptional response can cause transactivation. Such positive effects on transcription include the binding of an activated receptor to specific recognition sequences in the promoter of target genes to activate transcription. The activated receptors are capable of interacting specifically with DNA. The hormone- or ligand-activated receptors associate with specific DNA sequences, or hormone response elements, in the regulatory regions of target genes. Transactivation alters the rate of transcription or induces the transcription of a particular gene(s). It refers to an increase in the rate and/or amount of transcription taking place.

The terms "transrepress," "transrepression" or "transrepressing" as used herein refer to the negative effects on regulation of gene transcription due to the interaction of a hormone or ligand with a receptor inducing a cascade of molecular events that ultimately lead to the specific association of the activated receptor with other transcription factors such as NF κ -B or AP-1. Transrepression can occur from the interaction of non-natural as well as natural ligands. Antagonist and agonist compounds which interact with steroid hormone receptor can cause transrepression. Once the ligand binds to the receptor, a conformational change occurs. Transrepression can occur via two different mechanisms, i.e., through the dimeric and monomeric form of the receptor. Use of the monomeric form of the receptor for transrepression depends on the presence of the DNA binding domain but not on the ability of the receptor to bind DNA. Use of the dimeric form of the receptor for transrepression depends on the receptor binding response elements overlapping cis-element(s). Transrepression alters the rate of transcription or inhibits the transcription of a

particular gene. Transrepression decreases the rate and/or the amount of transcription taking place.

The term "progesterone receptor" as used herein also refers to a steroid hormone receptor which responds to or is activated by the hormone progesterone. Progesterone is part of the steroid hormone receptor superfamily as described above. The progesterone receptor can exist as two distinct but related forms that are derived from the same gene. The process for generation of the products may be alternate initiation of transcription, splicing differences, or transcription termination. These receptors are composed of DNA binding, ligand binding, as well as transregulatory domains. The progesterone receptor is also a ligand-dependent transcription factor capable of regulating gene expression. Interaction of the progesterone receptor with a ligand induces a cascade of molecular events that ultimately lead to the specific association of the activated receptor with regulatory elements of target genes.

The term "modified," "modification," "mutant" or "mutated" refers to an alteration of the receptor from its naturally occurring wild-type form. This includes alteration of the primary sequence of a receptor such that it differs from the wild-type or naturally-occurring sequence. The mutant steroid hormone receptor protein as used in the present invention can be a mutant of any member of the steroid hormone receptor superfamily. For example, a steroid receptor can be mutated by deletion of amino acids on the carboxyl terminal end of the protein. Generally, a deletion of from about 1 to about 120 amino acids from the carboxyl terminal end of the protein provides a mutant steroid hormone receptor useful in the present invention. A person having ordinary skill in this art will recognize, however, that a shorter deletion of carboxyl terminal amino acids will be necessary to create useful mutants of certain steroid hormone receptor proteins. Other mutations or deletions can be made in other

domains of the steroid receptor of interest, such as the DNA binding domain or the transregulatory domain.

For example, a mutant of the progesterone receptor protein will contain a carboxyl terminal amino acid deletion of approximately 1 to 60 amino acids. In a preferred embodiment of the present invention, 42 carboxyl terminal amino acids are deleted from the progesterone receptor protein. Likewise, a mutation of one or more amino acids in the DNA binding domain or the transregulatory domains can change the regulation of gene expression.

One skilled in the art will recognize that a combination of mutations and/or deletions are possible to gain the desired response. This would include double point mutations to the same or different domains. In addition, mutation also includes "null mutations" which are genetic lesions to a gene locus that totally inactivate the gene product.

Examples of mutations are described in PCT Publication PCT/US96/04324, the whole of which (including drawings) is hereby incorporated by reference.

The term mutation also includes any other derivatives. The term "derivative" as used herein refers to a peptide or compound produced or modified from another peptide or compound of a similar structure. Such a derivative may be a "chemical derivative," "fragment," "variant," "chimera," or "hybrid" of the complex. A derivative retains at least a portion of the function of the protein (for example reactivity with an antibody specific for the complex, enzymatic activity or binding activity mediated through noncatalytic domains) which permits its utility in accordance with the present invention.

A derivative may be a complex comprising at least one "variant" polypeptide which either lacks one or more amino acids or contain additional or substituted amino acids relative to the native polypeptide. The variant may be

derived from a naturally occurring complex component by appropriately modifying the protein DNA coding sequence to add, remove, and/or to modify codons for one or more amino acids at one or more sites of the C-terminus, N-terminus, and/or within the native sequence. It is understood that such variants having added, substituted and/or additional amino acids retain one or more characterizing portions of the native complex. A functional derivative of complexes comprising proteins with deleted, inserted and/or substituted amino acid residues may be prepared using standard techniques well-known to those of ordinary skill in the art.

A "chemical derivative" of the complex contains additional chemical moieties not normally a part of the protein. Such moieties may improve the molecule's solubility, absorption, biological half life, and the like.

The term "modified" or "modification" as used herein refers to a change in the composition or structure of the compound or molecule. However, the activity of the derivative, modified compound, or molecule is retained, enhanced, or increased relative to the activity of the parent compound or molecule. This would include the change of one amino acid in the sequence of the peptide or the introduction of one or more non-naturally occurring amino acids or other compounds. This includes a change in a chemical body, a change in a hydrogen placement, or any type of chemical variation. In addition, "analog" as used herein refers to a compound that resembles another structure. Analog is not necessarily an isomer. The above are only examples and are not limiting.

The term "nucleic acid sequence," "gene," "nucleic acid" or "nucleic acid cassette" as used herein refers to the genetic material of interest which can express a protein, or a peptide, or RNA after it is incorporated transiently, permanently, or episomally into a cell. The nucleic acid can be positionally and sequentially oriented in a vector with other necessary elements such that the

nucleic acid can be transcribed and, when necessary, translated into protein in the cells.

The term "genetic material" as used herein refers to contiguous fragments of DNA or RNA. The genetic material
5 which is introduced into targeted cells can be any DNA or RNA. For example, the nucleic acid can be: (1) normally found in the targeted cells, (2) normally found in targeted cells but not expressed at physiologically appropriate levels in targeted cells, (3) normally found
10 in targeted cells but not expressed at optimal levels in certain pathological conditions, (4) not normally found in the targeted cells, (5) novel fragments of genes normally expressed or not expressed in targeted cells, (6) synthetic modifications of genes expressed or not
15 expressed within targeted cells, (7) any other DNA which may be modified for expression in targeted cells and (8) any combination of the above.

The term "gene expression" or "nucleic acid expression" as used herein refers to the gene product of
20 the genetic material from the transcription and translation process. Expression includes the polypeptide chain translated from an mRNA molecule which is transcribed from a gene. If the RNA transcript is not translated, e.g., rRNA, tRNA, the RNA molecule represents
25 the gene product.

The expression of the glucocorticoid-progesterone fusion protein receptor can be expressed as a cell surface, cytoplasmic or nuclear protein. By "cell surface protein" it is meant that a protein is wholly or partially
30 spanning the cell membrane when expressed and which also is exposed on the surface of the cell. By cytoplasmic protein it is meant that a protein is contained completely within the cytoplasm, and does not span the nucleus or cell surfaces. As for "nuclear protein" it is meant that
35 the protein is wholly or partially spanning the nuclear membrane when expressed and is exposed to the cell cytoplasm, or may be contained completely within the cell

nucleus, not attached to the nuclear membrane and not exposed to cell cytoplasm.

In a preferred embodiment, the modified glucocorticoid receptor protein includes a mutated
5 progesterone ligand binding region of amino acids 640 through 914 of a progesterone receptor ligand binding domain. In another preferred embodiment, the modified glucocorticoid receptor protein contains a transregulatory domain located in the N-terminal region of the mutated
10 progesterone ligand binding domain. In another preferred embodiment, the modified glucocorticoid receptor protein includes a transregulatory domain located in the C-terminal region of the mutated progesterone ligand binding domain. Thus, the transregulatory domain can be located
15 either in the C-terminal or N-terminal direction of the ligand binding domain.

In another preferred embodiment, the modified glucocorticoid receptor protein includes a GAL4 DNA binding domain. In another preferred embodiment, the
20 modified glucocorticoid receptor protein includes a Krüppel-associated box-A (KRAB) transrepressing domain. The terms "GAL4 DNA binding domain" and "KRAB transrepressing domain" are used as conventionally understood in the art and encompass functional equivalents
25 of such sequences that retain the ability to bind DNA or retain the transrepressing activity.

In another preferred embodiment, the modified glucocorticoid receptor protein includes a mutated progesterone receptor ligand binding region capable of
30 binding RU486 at a concentration as low as 0.01 nM. In still another preferred embodiment, a modified steroid hormone receptor protein responds to a conventional antagonist of the wild-type steroid hormone receptor protein counterpart with an agonistic response. Those
35 skilled in the art will understand that "binding" can be measured by several conventional methods in the art, such as binding constants and that a protein "response" can

also be measured using conventional techniques in the art, such as measurement of induced transcription levels.

A second aspect of the present invention features a modified glucocorticoid receptor protein. The glucocorticoid receptor protein contains a DNA binding domain, transregulatory domains and a mutated ligand binding domain. The modified protein is capable of binding a non-natural ligand by the mutated ligand binding domain. The mutated ligand domain is created by deleting about 2-5 carboxyl terminal amino acids from the ligand binding domain. In a preferred embodiment, the modified glucocorticoid receptor protein can be mutated by deleting amino acids 762 and 763, and substituting or altering amino acids 752 and 753, of the ligand binding domain. Substituted amino acids 752 and 753 can be changed to be both alanines.

A third aspect of the present invention features a modified glucocorticoid receptor protein. This protein contains a DNA binding domain and transregulatory domains. The transregulatory domains are capable of constitutively transactivating or transrepressing gene expression. The receptor protein is mutated by removing the ligand binding domain. As used herein the term "constitutively" refers to the ability to continually activate or repress gene expression without the need for a ligand.

In a preferred embodiment, the modified glucocorticoid receptor protein activates target gene expression. In another preferred embodiment, the target gene encodes nerve growth factor.

A fourth aspect of the present invention features a modified glucocorticoid receptor protein. This protein is capable of binding a non-natural ligand. The modified receptor contains a glucocorticoid receptor region which comprises a DNA binding domain, a mutated transregulatory domain and a mutated ligand binding domain. The mutated transregulatory domains are capable of transactivating gene expression but not transrepressing gene expression.

Preferably the protein activates target gene expression and the target gene encodes nerve growth factor or functional equivalents thereof.

Examples of the mutated transregulatory domains are described in PCT Publication PCT/US96/04324, the whole of which (including drawings) is hereby incorporated by reference.

A fifth aspect of the present invention features a modified glucocorticoid receptor protein which is capable of binding a non-natural ligand. The modified receptor contains a glucocorticoid receptor region which comprises a mutated DNA binding domain, transregulatory domains and a mutated ligand binding domain. The mutated DNA binding domain prevents transactivation since DNA binding is necessary for such activation. The transregulatory domains are capable of transrepressing gene expression but not transactivating gene repression. Such activity occurs upon binding of the mutated binding ligand with the non-natural ligand.

Examples of the mutated DNA binding domain are described in PCT publication PCT/US96/04324, the whole of which (including drawings) is hereby incorporated by reference.

A sixth related aspect of the invention features a nucleic acid sequence encoding one of the modified glucocorticoid receptors as discussed above, including the fusion protein receptor. The nucleic acid is the genetic material which can express a protein, or a peptide, or RNA after it is incorporated transiently, permanently or episomally into a cell.

A seventh related aspect of the present invention features a vector containing a nucleic acid sequence for modified glucocorticoid receptors. The vectors are capable of expressing the nucleic acid transiently, permanently or episomally into a cell or tissue. In one example, the vector is a plasmid designated as pGR0403R

for the constitutively active GR and pGR0385 for mutated rat GR.

The term "vector" as used herein refers to a construction comprised of genetic material designed to direct transformation of a targeted cell. A vector contains multiple genetic elements positionally and sequentially oriented with other necessary elements such that the nucleic acid in a nucleic acid cassette can be transcribed and when necessary translated in the transfected cells. The term vector as used herein can refer to nucleic acid, e.g., DNA derived from a plasmid, cosmid, phagemid or bacteriophage, into which one or more fragments of nucleic acid may be inserted or cloned which encode for particular proteins. The term "plasmid" as used herein refers to a construction comprised of extrachromosomal genetic material, usually of a circular duplex of DNA which can replicate independently of chromosomal DNA. The plasmid does not necessarily replicate.

The vector can contain one or more unique restriction sites, and may be capable of autonomous replication in a defined host or organism such that the cloned sequence is reproduced. The vector molecule can confer some well-defined phenotype on the host organism which is either selectable or readily detected. The vector may have a linear or circular configuration. The components of a vector can contain but is not limited to a DNA molecule incorporating: (1) DNA; (2) a sequence encoding a therapeutic or desired product; and (3) regulatory elements for transcription, translation, RNA processing, RNA stability, and replication.

The purpose of the vector is to provide expression of a nucleic acid sequence in cells or tissue. Expression includes the efficient transcription of an inserted gene or nucleic acid sequence. Expression products may be proteins, polypeptides, or RNA. The nucleic acid sequence can be contained in a nucleic acid cassette. Expression

of the nucleic acid can be continuous, constitutive, or regulated. The vector can also be used as a prokaryotic element for replication of plasmid in bacteria and selection for maintenance of plasmid in bacteria.

5 In the present invention the preferred vector comprises the following elements linked sequentially at an appropriate distance to allow functional expression: a promoter, a 5' mRNA leader sequence, a translation initiation site, a nucleic acid cassette containing the
10 sequence to be expressed, a 3' mRNA untranslated region, and a polyadenylation signal sequence. As used herein the term "expression vector" refers to a DNA vector that contains all of the information necessary to produce a recombinant protein in a heterologous cell.

15 In addition, the term "vector" as used herein can also include viral vectors. A "viral vector" in this sense is one that is physically incorporated in a viral particle by the inclusion of a portion of a viral genome within the vector, e.g., a packaging signal, and is not
20 merely DNA or a located gene taken from a portion of a viral nucleic acid. Thus, while a portion of a viral genome can be present in a vector of the present invention, that portion does not cause incorporation of the vector into a viral particle and thus is unable to
25 produce an infective viral particle.

A vector as used herein can also include DNA sequence elements which enable extra-chromosomal (episomal) replication of the DNA. Vectors capable of episomal replication are maintained as extra-chromosomal molecules and can
30 replicate. These vectors are not eliminated by simple degradation but continue to be copied. These elements may be derived from a viral or mammalian genome. These provide prolonged or "persistent" expression as described below.

35 The term "persistent expression" as used herein refers to introduction of genes into the cell together with genetic elements which enable episomal (i.e., extra-

chromosomal) replication. This can lead to apparently stable transformation of the cell without the integration of the novel genetic material into the chromosome of the host cell.

5 "Stable expression" as used herein relates to the integration of genetic material into chromosomes of the targeted cell where it becomes a permanent component of the genetic material in that cell. Gene expression after stable integration can permanently alter the character-
10 istics of the cell and its progeny arising by replication leading to stable transformation.

An eighth related aspect of the present invention features a transfected cell containing a vector which contains nucleic acid sequence for a modified gluco-
15 corticoid receptor as discussed above. As used herein the term "transfected" or "transfection" refers to the incorporation of foreign DNA into any cells by exposing them to such DNA. This would include the introduction of DNA by various delivery methods, e.g., via vectors or
20 plasmids.

Methods of transfection may include microinjection, CaPO₄ precipitation, liposome fusion (e.g., lipofection), electroporation or use of a gene gun. Those are only examples and are meant not to be limiting. The term
25 "transfection" as used herein refers to the process of introducing DNA (e.g., DNA expression vector) into a cell. Following entry into the cell, the transfected DNA may: (1) recombine with the genome of the host; (2) replicate independently as an episome; or (3) be maintained as an
30 episome without replication prior to elimination. Cells may be naturally able to uptake DNA. Particular cells which are not naturally able to take up DNA require various treatments, as described above, in order to induce the transfer of DNA across the cell membrane.

35 A ninth related aspect of the present invention features a transformed cell with a vector containing a nucleic acid sequence for a modified glucocorticoid

receptor as discussed above. As used here in the term "transformed" or "transformation" refers to transient, stable or permanent changes in the characteristics (expressed phenotype) of a cell by the mechanism of gene transfer. Genetic material is introduced into a cell in a form where it expresses a specific gene product or alters the expression or effects of endogenous gene products.

The term "stable" as used herein refers to the introduction of gene(s) into the chromosome of the targeted cell where it integrates and becomes a permanent component of the genetic material in that cell. Gene expression after stable transformation can permanently alter the characteristics of the cell leading to stable transformation. An episomal transformation is a variant of stable transformation in which the introduced gene is not incorporated in the host cell chromosomes but rather is replicated as an extrachromosomal element. This can lead to apparently stable transformation of the characteristics of a cell. "Transiently" as used herein refers to the introduction of a gene into a cell to express the nucleic acid, e.g., the cell express specific proteins, peptides or RNA, etc. The introduced gene is not integrated into the host cell genome and is accordingly eliminated from the cell over a period of time. Transient expression relates to the expression of a gene product during a period of transient transfection. Transient expression also refers to transfected cells with a limited life span.

Transformation can be performed by *in vivo* techniques or *ex vivo* techniques as described in PCT Publication PCT/US96/04324, the whole of which (including drawings) is hereby incorporated by reference. Transformation can be tissue specific to regulate expression of the nucleic acid predominantly in the tissue or cell of choice.

Transformation of the cell may be associated with production of a variety of gene products including protein and RNA. Such products are described in PCT Publication

PCT/US96/04324, the whole of which (including drawings) is hereby incorporated by reference. The product expressed by the transformed cell depends on the nucleic acid of the nucleic acid cassette. In the present invention the
5 nucleic acid to be expressed is a fusion protein as referenced above, or variations thereof or any of the other receptor proteins disclosed herein.

In one embodiment the transformed cell is a muscle cell. The term "muscle" refers to myogenic cells
10 including myoblasts, skeletal, heart and smooth muscle cells. The muscle cells or tissue can be *in vivo*, *in vitro* or tissue culture and capable of differentiating into muscle tissue. In another embodiment, the transformed cell is a lung cell. The term "lung cell" as
15 used herein refers to cells associated with the pulmonary system. The lung cell can also be *in vivo*, *in vitro* or tissue culture.

In still another embodiment, the transformed cell is a cell associated with the joints. The term "cells
20 associated with the joints" refers to all of the cellular and non-cellular materials which comprise the joint (e.g., knee or elbow) and are involved in the normal function of the joint or are present within the joint due to pathological conditions. These include material
25 associated with: the joint capsule such as synovial membranes, synovial fluid, synovial cells (including type A cells and type B synovial cells); the cartilaginous components of the joint such as chondrocyte, extracellular matrix of cartilage; the bony structures such as bone,
30 periosteum of bone, periosteal cells, osteoblast, osteoclast; the immunological components such as inflammatory cells, lymphocytes, mast cells, monocytes, eosinophil; other cells like fibroblasts; and combinations of the above. Once transformed these cells express the
35 fusion protein. One skilled in the art will quickly realize that any cell is capable of undergoing transformation and within the scope of this invention.

A tenth aspect of the present invention features methods for transforming a cell with a vector containing nucleic acid encoding for a modified glucocorticoid receptor. This method includes the steps of transforming
5 a cell in situ by contacting the cell with the vector for a sufficient amount of time to transform the cell. As discussed above, transformation can be *in vivo* or *ex vivo*. Once transformed the cell expresses the mutated glucocorticoid receptor. This method includes methods of
10 introducing and methods of incorporating the vector. "Incorporating" and "introducing" as used herein refer to uptake or transfer of the vector into a cell such that the vector can express the therapeutic gene product within a cell as discussed with transformation above.

15 An eleventh aspect of the present invention features a method of using the modified glucocorticoid receptors discussed above. This method comprises the steps of transforming a cell with a vector containing a nucleic acid encoding for the modified glucocorticoid receptor of
20 interest. The transformed cells are able to express the mutated glucocorticoid receptor. The receptor is capable of regulating by a non-natural ligand the expression of glucocorticoid responsive genes, whether such regulation is transactivation or transrepression. The term
25 "glucocorticoid responsive genes" as used herein refers to genes whose expression is regulated by the activation of the glucocorticoid receptor. Such regulation includes both positive and negative regulation of gene expression. This also includes GRE (glucocorticoid response element)
30 controlled genes.

This method of use includes methods of gene replacement using the fusion protein, methods of gene therapy using the fusion protein and methods of administering the fusion protein in which the same steps
35 are used. "Gene replacement" as used herein means supplying a nucleic acid sequence which is capable of being expressed *in vivo* in an animal and thereby providing

or augmenting the function of an endogenous gene which is missing or defective in the animal.

The methods of use also include methods for using the modified glucocorticoid receptor to activate GRE controlled genes. Such genes can be co-transfected with the modified glucocorticoid receptors. Such co-transfection allows activated expression of the GRE controlled genes. Furthermore, the methods of use include the use of tissue specific delivery systems, and use of mRNA stability constructs.

The present invention features methods for administration as discussed above. Such methods include methods for administering a supply of polypeptide, protein or RNA to a human, animal or to tissue culture or cells. These methods of use of the above-referenced vectors comprises the steps of administering an effective amount of the vectors to a human, animal or tissue culture. The term "administering" or "administration" as used herein refers to the route of introduction of a vector or carrier of DNA into the body. The vectors of the above methods and the methods discussed below may be administered by various routes. Administration may be intravenous, intratissue injection, topical, oral, or by gene gun or hypospray instrumentation. Administration can be directly to a target tissue, e.g. direct injection into synovial cavity or cells, or through systemic delivery. These are only examples and are nonlimiting.

Administration will include a variety of methods, as described in PCT Publication PCT/US96/04324, the whole of which (including drawings) is hereby incorporated by reference. See, also, WO 93/18759, the whole of which is hereby incorporated by reference. The preferred embodiment is by direct injection. Routes of administration include intramuscular, aerosol, oral, topical, systemic, ocular, intraperitoneal, intrathecal and/or fluid spaces.

The term "effective amount" as used herein refers to sufficient vector administered to humans, animals or into

tissue culture cells to produce the adequate levels of polypeptide, protein, or RNA. One skilled in the art recognizes that the adequate level of protein polypeptide or RNA will depend on the intended use of the particular
5 vector. These levels will be different depending on the type of administration, treatment or vaccination as well as intended use.

In one embodiment of the present invention, the method of using the mutated glucocorticoid receptors
10 discussed above uses RU486 as the non-natural ligand to regulate gene expression. This ligand is capable of binding the mutated progesterone or glucocorticoid ligand binding domain and activating the transregulatory domains of the receptor. RU486 is capable of activating or
15 repressing the appropriate glucocorticoid responsive genes. This is only an example and is not meant to be limiting. Those skilled in the art will recognize that other non-natural ligands can be used.

The method of use can regulate transactivation of
20 glucocorticoid responsive genes or GRE controlled genes or gene constructs. In addition, the method of use can regulate transrepression of glucocorticoid responsive genes such as metalloproteinases, interleukins, cyclo-oxygenases, and cytokines. Although such genes respond to
25 other stimuli, these genes are repressed by steroids. Typically, without the primary stimulant, steroids have little effect on the basal transcription of such genes. Genes such as IL-2, IL-6, IL-8, ICAM-1, VCAM-1 have been repressed by steroids. Any gene transcription depending
30 on AP-1 or NF κ -B will be repressed in the present invention.

A twelfth aspect of the present invention features a method for treating arthritis. This method includes the transformation of cells associated with the joints with
35 the above referenced vectors. The vectors contain nucleic acid which encode for the modified glucocorticoid receptor protein. Once expressed in the cells associated with the

joints, the mutated protein is capable of transactivating or transrepressing by a non-natural ligand the expression of glucocorticoid responsive genes or GRE controlled genes, including transfected GRE controlled gene constructs. Treatment of arthritis is further described in PCT Publication PCT/US96/04324, the whole of which (including drawings) is hereby incorporated by reference.

A thirteenth aspect of the present invention features a method for treating asthma. This method includes the transformation of cells associated with the lungs or pulmonary system with the above referenced vectors. The vectors contain nucleic acid which encodes the fusion protein. Once expressed in the lung cells the mutated receptor is capable of transactivating or transrepressing the expression by a non-natural ligand of the appropriate glucocorticoid responsive genes and/or GRE controlled transgenes.

In one embodiment, the above methods of treatment invoke use of RU486 as the non-natural ligand. The transactivation and transrepression can occur when the mutated glucocorticoid receptor is activated by RU486. The genes that are transrepressed or transactivated in response to ligand binding to the fusion protein are described above.

A fourteenth aspect of the present invention features a transgenic animal whose cells contain the vectors of the present invention. These cells include germ or somatic cells. Transgenic animal models can be used for understanding of molecular carcinogenesis and disease, assessing and exploring novel therapeutic avenues for effects by potential chemical and physical carcinogens and tumor promoters.

An additional preferred embodiment provides for a transgenic animal containing a modified glucocorticoid receptor vector. By "transgenic animal" is meant an animal whose genome contains an additional copy or copies of the gene from the same species or it contains the gene

or genes of another species, such as a gene encoding for a mutated glucocorticoid receptor introduced by genetic manipulation or cloning techniques, as described herein and as known in the art. The transgenic animal can include the resulting animal in which the vector has been inserted into the embryo from which the animal developed or any progeny of that animal. The term "progeny" as used herein includes direct progeny of the transgenic animal as well as any progeny of succeeding progeny. Thus, one skilled in the art will readily recognize that if two different transgenic animals have been made each utilizing a different gene or genes and they are mated, the possibility exists that some of the resulting progeny will contain two or more introduced genes. One skilled in the art will readily recognize that by controlling the matings, transgenic animals containing multiple introduced genes can be made.

Other features and advantages of the invention will be apparent from the following description of the preferred embodiments thereof and from the claims.

Brief Description of the Drawings

The drawings are not necessarily to scale. Certain features of the invention may be exaggerated in scale or shown in schematic form in the interest of clarity and conciseness.

Detailed Description of the Invention

The present invention provides modified proteins of steroid hormone receptors. Steroid hormone receptors which may be modified include any of those receptors which
5 comprise the steroid hormone receptor superfamily. Representative examples of such receptors include the estrogen, progesterone, glucocorticoid, mineralocorticoid, androgen, thyroid hormone, retinoic acid, retinoid X and Vitamin D3 receptors.

10 The modified steroid hormone receptor proteins of the present invention include a steroid receptor region made up of a DNA binding domain, one or more transregulatory domains and a mutated steroid receptor ligand binding region capable of binding a non-natural ligand.

15 The DNA binding domain contains the receptor regulating sequence and binds DNA. Such a domain may be a yeast GAL4 DNA binding domain. The ligand binding domain binds the specific compound which will activate the receptor, for example RU486.

20 Several different functional domains have been characterized in transcription factors; they can be either acidic (VP16, GAL4), glutamine-rich (SP1, Oct-1, Oct2A), proline-rich (Oct3/4), or serine- and threonine-rich (Pit1) (Wegner et al., *Curr. Opin. in Cell Biol.* 5:488-
25 498 (1993)). It is known that different types of transcriptional activation domains interact with different coactivators of the general transcriptional machinery. When different activation domains are fused together in a transactivator, they can synergize with each other to
30 increase its transcriptional potential. Recently, Gerber, et al. demonstrated that insertion of either a poly-glutamine (poly-Q) or poly-proline (poly-P) stretch within the GAL4-VP16 enhances the activation of GAL4-VP16 (Gerber et al., *Science* 263:808-811 (1994)).

35 In order to increase the potency of the GLVP regulator, varying lengths of poly-Q stretches encoded by the triplet repeats (CAG)_n were inserted into the N-

terminus of the GLVP regulator (Figure 14). Transactivation analysis of the various sizes of poly-Q insertions in the GLVP indicate that addition of 10-34Q increases transcriptional activity of the regulator on the reporter
5 gene (17x4-TATA-hGH), while further extension of poly-Q from a 66Q-oligomer to a 132Q-oligomer results in decreased activation of target gene (Figure 15). These experiments demonstrated that a combination of different types of functional domains of appropriate strength
10 further improves the activation potential of the GLVP chimeric regulator.

To understand whether additional activation domains of the same type would also increase the activation potential of the chimeric regulator, GLVPx2 with 2 copies
15 of VP16 activation domain at the N-terminus was constructed (Figure 14). As shown in Figure 16, further addition of the same type of transactivation domain (VP16) did not increase the activation potential of the regulator.

20 The original GLVP can efficiently activate target gene expression containing stronger promoters such as the thymidine kinase (tk) promoter. To further enhance the transcriptional activity of GLVP, a more potent RU486-inducible gene regulator was generated. This new gene
25 regulator responds to RU486 at a concentration even lower than that used by the original GLVP. At this concentration, RU486 does not have any anti-progesterone or anti-glucocorticoid activity. The inducible system has been used successfully to produce secreted NGF from a
30 reporter gene in an RU486 dependent manner to induce neurite outgrowth in co-cultured PC12 cells (of rat adrenal pheochromocytoma). This RU486-controllable ligand binding domain can also be converted to an inducible repressor for shutting down target gene expression.
35 Individual domains within a chimeric fusion protein have been shown to influence each other's function in a position-dependent context.

Transcriptional regulation of gene expression has been intensively studied over the past decade (McKnight, *Genes Dev.* 10:367-381; Goodrich et al., *Curr. Opin. in Cell Biol.* 6:403-409; Pugh, *Curr. Opin. in Cell Biol.* 8:303-311). It is generally believed that transcription factors selectively bind to their recognition sequences on DNA (promoters and enhancers) and directly interact with the TBP-associated factors (TAFs), coactivators, or corepressors to activate or repress transcriptional activity. Nuclear hormone receptors, such as steroid, thyroid, retinoid and orphan receptors, are an unique class of inducible transcription factors that can modulate their respective target genes in response to their cognate ligands. Recently, several coactivators (SRC-1) (Onate et al., *Science* 270:1354-1357 (1995)), CBP (Kamei et al., *Cell* 85:403-414 (1996)), and corepressors (N-CoR, SMART) (Hörlein et al., *Nature* 377:397-404 (1995); Chen et al., *Nature* 377:454-457 (1995)), that mediate nuclear hormone receptor activation of target genes have been identified. These studies suggest that multiple protein factors are involved in the complex process of transcriptional regulation of gene expression.

Mutagenesis studies of the hPR ligand binding domain have demonstrated that extension of the LBD deletion from amino acid position 891 to 914 increases the activation potential of the chimeric regulator. Addition of this short stretch of 23 amino acids increases the PR-LBD's dimerization potential and subsequent binding to its response element. Further extension of the hPR-LBD from residue 917 to 928 results in a decrease of trans-activation, suggesting that this region may serve as a repressor interacting domain. In fact, when this 12 amino acid stretch is ligated to the GAL4 DNA binding domain, it is sufficient to confer transcriptional repression of a target gene, suggesting that these 12 amino acids might interact with a yet unidentified cellular co-repressor (Xu et al., (unpublished) (1996)).

Many chimeric proteins have been constructed in recent years in order to combine different functional domains of various proteins into one versatile chimera. While it is clear that each protein domain can function independently, relatively little is known about how individual domains modulate each other's function within a chimeric protein. The activation potential of VP16 is influenced by its relative position within the chimeric regulator. The C-terminally located VP16 chimeric regulator GL₉₁₄VP_C effectively activates target gene expression containing a minimal promoter at an RU486 concentration 10-fold lower than its N-terminally located VP16 counterpart, GL₉₁₄VP. At this concentration, RU486 is expected to have no interference with endogenous gene expression.

This new inducible system will afford an improved margin of safety and further contribute to its application for gene regulation *in vivo*. Mutational studies revealed that the chimeric regulator GL₉₁₄VP_C is about 8 to 10 times more potent than our originally described regulator GLVP and responds at a lower ligand concentration. Furthermore, within a chimeric protein, individual functional domains, such as those involved in transactivation, DNA binding and ligand binding, can modulate each other's function, depending on their relative positions.

Protein-protein interaction studies suggest that different types of transactivation or transrepression domains interact with their respective TAFs or coactivator, corepressor molecules within the RNA polymerase II preinitiation complex to alter gene transcription (Pugh, *Curr. Opin. in Cell Biol.* 8:303-311; Goodrich et al., *Cell* 75:519-530 (1993)). Glutamine rich stretches have been identified in various transcriptional factors (SP1, Oct-1 and androgen receptor) although their precise function is unknown (Wegner et al., *Curr. Opin. in Cell Biol.* 5:488-498 (1993); Gerber et al., *Science* 263:808-811 (1994)). Expanded regions of triplet CAG repeats have been

implicated in several neurodegenerative diseases such as Huntington's, Kennedy's, dentatorubral-pallidoluysian atrophy (DRPLA), and hereditary spinocerebellar ataxias (SCA1) (Kuhl et al., *Curr. Opin. in Genet. Dev.* 3:404-407 (1993); Ross et al., *Trends in Neurosci* 16:254-260 (1993)); Ashley et al., *Annu. Rev. Genet.* 29:703-728 (1995)).

Recently, several groups have isolated proteins responsible for the above mentioned neurodegenerative diseases and confirmed that they indeed contain long poly-glutamine (Q) stretches encoded by the expanded CAG repeats (Servadio et al., *Nature Genet.* 10:94-98 (1995); Yazawa et al., *Nature Genet.* 10:99-103 (1995); Trottier et al., *Nature Genet.* 10:104-110 (1995)). To further understand the role of poly-Q stretches in transcriptional regulation, various lengths of poly-Q was inserted in the N-terminus of GLVP.

Addition of a 10-34 oligomer of poly-Q results in synergistic transcriptional activation, while expanded CAG triplet repeats beyond 66 oligomeric glutamines do not further increase the transactivation potential of chimeric regulator GLVP. These observations suggest that structural and conformational changes might be involved in proteins encoded by the expanded CAG triplet repeat as compared with the regular length poly-Q which encoded by 10-30 repeats of CAG in normal protein. These results suggest that a neurological disease with expanded CAG repeats (>40 mer) may not be due to aberrant high transcriptional potential but rather due to an influence on other aspects of cell function (Burke et al., *Nature Medecine* 2:347-350 (1996)).

A transcription factor can either activate or repress gene expression depending on the promoter/enhancer context of its particular target DNA and the coregulator proteins with which it interacts (Kingston et al. *Genes Dev.* 10:905-920 (1996)). For example, in the absence of thyroid hormone (T3), the thyroid hormone receptor (TR)

normally binds to its recognition sequence on DNA and represses target gene activation through interactions with corepressors (Baniahmad et al., *Mol. Cell. Biol.* 15:76-86 (1995); Shibata et al. (unpublished) (1996); Chen et al.,
5 *Nature* 377:454-457 (1995)). In the presence of T3, the co-repressor is released from the receptor and coactivators are recruited to enhance gene expression. Many transcription factors, such as p53, WT-1, YY1, Rel,
10 on the DNA template and protein co-factors with which they interact.

The *Drosophila* zinc finger transcription factor, Krüppel, is encoded by a gap gene and is essential for organogenesis during later stages of the development.
15 Through *in vitro* protein-protein interaction studies, Sauer et al. have demonstrated that the Krüppel protein can act as a transcriptional activator at low protein concentration (monomeric form) by interacting with TFIIB. However, at higher protein concentration, Krüppel forms a
20 dimer and directly interacts with TFIIE β resulting in transcriptional repression. Several Krüppel related proteins recently have been identified in mammalian cells (Witzgall et al., *Mol. Cell. Biol.* 13:1933-42 (1993); Witzgall et al., *Proc. Natl. Acad. Sci.* 91:4514-4518
25 (1994); Margolin et al., *Proc. Natl. Acad. Sci.* 91:4509-4513 (1994)). One of them, Kid-1, was isolated from rat kidney and contains a highly conserved region of ~75 amino acids at the N-terminus termed Krüppel-associated box (KRAB).

30 It has been shown that the KRAB domain can act as a potent repressor when fused to a yeast GAL4 DNA binding domain or TetR (Deuschle et al., *Mol. Cell. Biol.* 15:1907-1914 (1995)). Replacement of the VP16 transcriptional activation domain with the Kid-1 KRAB repression domain,
35 converted a regulatable transactivator into a regulatable repressor. By exchanging the GAL4 DNA binding domain with the DNA binding domain of another protein, repression of

a target gene (e.g., tumor proliferation gene) may be achieved in response to ligand RU486. Recently, Deuschle et al. reported that the KRAB domain isolated from Kox1 zinc finger protein, which shares extensively homology with that of Kid-1, interacts with a 110 kDa adaptor protein termed SMP1 (silencing-mediating protein 1). The characteristics and mechanism of this adaptor protein have yet to be determined. Recently, a KRAB-associated protein-1 (KAP-1) was identified which binds to the KRAB domain and functions as a transcriptional co-repressor (Friedman et al., *Gene and Dev.* 10:2067 (1996)).

Using the newly modified $GL_{914}VP_C$, regulation of neurite outgrowth in PC12 cells via RU486 controllable expression of NGF was achieved. This novel inducible system can be employed to analyze biological function in a temporal manner. For example, the role of a growth factor could be assessed at a particular stage of development and the sequential relationship of *in vivo* cell death and proliferation could be delineated in a manner not possible with constitutive expression of the test gene.

Tissue specific regulation of gene expression in transgenic mice utilizing this inducible system was demonstrated. RU486 inducible regulator may be used to create an inducible gene knockout (temporal and/or spatial) in transgenic mice which could circumvent an embryonic lethality resulting from use of current gene knockout techniques. Combinatorial inclusion of other inducible systems such as the tetracycline or ecdysone system with the RU486 inducible system may allow biologists one day to modulate complex biological processes which involve multiple levels of control.

The following are examples of the present invention using the mutated steroid receptors for gene therapy. It will be readily apparent to one skilled in the art that various substitutions and modifications may be made to the invention disclosed herein without departing from the

scope and spirit of the invention. Thus, these examples are offered by way of illustration and are not intended to limit the invention in any manner.

The following are specific examples of preferred
5 embodiments of the present invention. These examples demonstrate how the molecular switch mechanisms of the present invention can be used in construction of various cellular or animal models and how such molecular switch mechanisms can be used to transactivate or transrepress
10 the regulation of gene expression. The utility of the molecular switch molecules is noted herein and is amplified upon in related applications by O'Malley et al, entitled "Modified Steroid Hormones for Gene Therapy and Methods for Their Use," and by Vegeto, et al., entitled
15 "Mutated Steroid Hormone Receptors, Methods for Their Use and Molecular Switch for Gene Therapy," supra and in a related U.S. Patent by Vegeto, et al., entitled "Progesterone Receptor Having C-Terminal Hormone Binding Domain Truncations," supra. Such sections (including
20 drawings) are hereby specifically incorporated by reference herein.

Methods of Use

Cell Transformation

One embodiment of the present invention includes
25 cells transformed with nucleic acid encoding for the mutated receptor. Once the cells are transformed, the cells will express the protein, polypeptide, or RNA encoded for by the nucleic acid. Cells include but are not limited to joints, lungs, muscle and skin. This is
30 not intended to be limiting in any manner.

The nucleic acid which contains the genetic material of interest is positionally and sequentially oriented within the host or vectors such that the nucleic acid can be transcribed into RNA and, when necessary, be translated
35 into proteins or polypeptides in the transformed cells. A variety of mutated glucocorticoid proteins and poly-

peptides can be expressed by the sequence in the nucleic acid cassette in the transformed cells.

Transformation can be done either by *in vivo* or *ex vivo* techniques. One skilled in the art will be familiar with such techniques for transformation. Transformation by *ex vivo* techniques includes co-transfecting the cells with DNA containing a selectable marker. This selectable marker is used to select those cells which have become transformed. Selectable markers are well known to those who are skilled in the art.

For example, one approach to gene therapy for muscle diseases is to remove myoblasts from an affected individual, genetically alter them *in vitro*, and reimplant them into a receptive locus. The *ex vivo* approach includes the steps of harvesting myoblasts cultivating the myoblasts, transducing or transfecting the myoblasts, and introducing the transfected myoblasts into the affected individual.

The myoblasts may be obtained in a variety of ways. They may be taken from the individual who is to be later injected with the myoblasts that have been transformed or they can be collected from other sources, transformed and then injected into the individual of interest.

Once the *ex vivo* myoblasts are collected, they may be transformed by contacting the myoblasts with media containing the nucleic acid transporter and maintaining the cultured myoblasts in the media for sufficient time and under conditions appropriate for uptake and transformation of the myoblasts. The myoblasts may then be introduced into an appropriate location by injection of cell suspensions into tissues. One skilled in the art will recognize that the cell suspension may contain: salts, buffers or nutrients to maintain viability of the cells; proteins to ensure cell stability; and factors to promote angiogenesis and growth of the implanted cells.

In an alternative method, harvested myoblasts may be grown *ex vivo* on a matrix consisting of plastics, fibers

or gelatinous materials which may be surgically implanted in an appropriate location after transduction. This matrix may be impregnated with factors to promote angiogenesis and growth of the implanted cells. Cells can
5 then be reimplanted.

Administration

Administration as used herein refers to the route of introduction of a vector or carrier of DNA into the body. Administration may include intravenous, intramuscular,
10 topical, or oral methods of delivery. Administration can be directly to a target tissue or through systemic delivery.

In particular, the present invention can be used for treating disease or for administering the formulated DNA
15 expression vectors capable of expressing any specific nucleic acid sequence. Administration can also include administering a regulatable vector discussed above. Such administration of a vector can be used to treat disease. The preferred embodiment is by direct injection to the
20 target tissue or systemic administration.

A second critical step is the delivery of the DNA vector to the nucleus of the target cell where it can express a gene product. In the present invention this is accomplished by formulation. The formulation can consist
25 of purified DNA vectors or DNA vectors associated with other formulation elements such as lipids, proteins, carbohydrates, synthetic organic or inorganic compounds. Examples of such formulation elements include, but are not limited to, lipids capable of forming liposomes, cationic
30 lipids, hydrophilic polymers, polycations (e.g., protamine, polybrene, spermidine, polylysine), peptide or synthetic ligands recognizing receptors on the surface of the target cells, peptide or synthetic ligands capable of inducing endosomal lysis, peptide or synthetic ligands
35 capable of targeting materials to the nucleus, gels, slow release matrices, soluble or insoluble particles, as well

as other formulation elements not listed. This includes formulation elements for enhancing the delivery, uptake, stability, and/or expression of genetic material into cells.

5 The delivery and formulation of any selected vector construct will depend on the particular use for the expression vectors. In general, a specific formulation for each vector construct used will focus on vector uptake with regard to the particular targeted tissue, followed by
10 demonstration of efficacy. Uptake studies will include uptake assays to evaluate cellular uptake of the vectors and expression of the tissue specific DNA of choice. Such assays will also determine the localization of the target DNA after uptake, and establish the requirements for
15 maintenance of steady-state concentrations of expressed protein. Efficacy and cytotoxicity can then be tested. Toxicity will not only include cell viability but also cell function.

 DNA uptake by cells associated with fluid spaces have
20 the unique ability to take up DNA from the extracellular space after simple injection of purified DNA preparations into the fluid spaces. Expression of DNA by this method can be sustained for several months.

 Incorporating DNA by formulation into particulate
25 complexes of nanometer size that undergo endocytosis increases the range of cell types that will take up foreign genes from the extracellular space.

 Formulation can also involve DNA transporters which are capable of forming a non-covalent complex with DNA and
30 directing the transport of the DNA through the cell membrane. This may involve the sequence of steps including endocytosis and enhanced endosomal release. It is preferable that the transporter also transport the DNA through the nuclear membrane. See, e.g., the following
35 applications all of which (including drawings) are hereby incorporated by reference herein: (1) Woo et al., U.S. Serial No. 07/855,389, entitled "A DNA Transporter System

and Method of Use" filed March 20, 1992; (2) Woo et al., PCT/US93/02725, entitled "A DNA Transporter System and Method of Use", (designating the U.S. and other countries) filed March 19, 1993; and (3) continuation-in-part application by Woo et al., entitled "Nucleic Acid Transporter Systems and Methods of Use", filed December 14, 1993, assigned U.S. Serial Number 08/167,641.

In addition, delivery can be cell specific or tissue specific by including cell or tissue specific promoters. Furthermore, mRNA stabilizing sequences (3' UTR's) can be used to provide stabilized modified receptor molecules. Such stabilizing sequences increase the half-life of mRNAs and can be cell or tissue specific. The above is discussed in more detail in U.S. Patent 5,298,422 (Schwartz et al.) and U.S. Application Serial Number 08/209,846 (Schwartz et al.), filed March 9, 1994, entitled "Expression Vector Systems and Method of Use." Both of these, the whole of which, are incorporated by reference herein, including drawings.

In a preferred method of administration involving a DNA transporter system, the DNA transporter system has a DNA binding complex with a binding molecule capable of non-covalently binding to DNA which is covalently linked to a surface ligand. The surface ligand is capable of binding to a cell surface receptor and stimulating entry into the cell by endocytosis, pinocytosis, or potocytosis. In addition, a second DNA binding complex is capable of non-covalently binding to DNA and is covalently linked to a nuclear ligand. The nuclear ligand is capable of recognizing and transporting a transporter system through a nuclear membrane. Additionally, a third DNA binding complex may be used which is also capable of non-covalently binding to DNA. The third binding molecule is covalently linked to an element that induces endosomal lysis or enhanced release of the complex from the endosome after endocytosis. The binding molecules can be spermine, spermine derivatives, histones, cationic peptides and/or

polylysine. See also Szoka, C.F., Jr. et al., Bioconjug. Chem. 4:85-93 (1993); Szoka, F.C., Jr. et al., P.N.A.S., 90:893-897 (1993).

Transfer of genes directly has been very effective.
5 Experiments show that administration by direct injection of DNA into joint tissue results in expression of the gene in the area of injection. Injection of plasmids containing the mutated receptors into the spaces of the joints results in expression of the gene for prolonged
10 periods of time. The injected DNA appears to persist in an unintegrated extrachromosomal state. This means of transfer is the preferred embodiment.

The formulation used for delivery may also be by liposomes or cationic lipids. Liposomes are hollow
15 spherical vesicles composed of lipids arranged in a similar fashion as those lipids which make up the cell membrane. They have an internal aqueous space for entrapping water soluble compounds and range in size from 0.05 to several microns in diameter. Several studies have
20 shown that liposomes can deliver nucleic acids to cells and that the nucleic acid remains biologically active. Cationic lipid formulations such as formulations incorporating DOTMA has been shown to deliver DNA expression vectors to cells yielding production of the corresponding
25 protein. Lipid formulations may be non-toxic and biodegradable in composition. They display long circulation half-lives and recognition molecules can be readily attached to their surface for targeting to tissues. Finally, cost effective manufacture of liposome-based
30 pharmaceuticals, either in a liquid suspension or lyophilized product, has demonstrated the viability of this technology as an acceptable drug delivery system. See Szoka, F.C., Jr. et al., Pharm. Res., 7:824-834 (1990); Szoka, F.C., Jr. et al., Pharm. Res., 9:1235-1242
35 (1992).

The chosen method of delivery should result in nuclear or cytoplasmic accumulation and optimal dosing.

The dosage will depend upon the disease and the route of administration but should be between 1-1000 $\mu\text{g/kg}$ of body weight. This level is readily determinable by standard methods. It could be more or less depending on the optimal dosing. The duration of treatment will extend through the course of the disease symptoms, possibly continuously. The number of doses will depend upon disease, the formulation and efficacy data from clinical trials.

With respect to vectors, the pharmacological dose of a vector and the level of gene expression in the appropriate cell type includes but is not limited to sufficient protein or RNA to either: (1) increase the level of protein production; (2) decrease or stop the production of a protein; (3) inhibit the action of a protein; (4) inhibit proliferation or accumulation of specific cell types; and (5) induce proliferation or accumulation of specific cell types. As an example, if a protein is being produced which causes the accumulation of inflammatory cells within the joint, the expression of this protein can be inhibited, or the action of this protein can be interfered with, altered, or changed.

Persistent Expression Using Episomal Vectors

In each of the foregoing examples, transient expression of recombinant genes induces the desired biological response. In some diseases more persistent expression of recombinant genes is desirable. This is achieved by adding elements which enable extrachromosomal (episomal) replication of DNA to the structure of the vector. Vectors capable of episomal replication are maintained as extrachromosomal molecules and can replicate. These sequences will not be eliminated by simple degradation but will continue to be copied. Episomal vectors provide prolonged or persistent, though not necessarily stable or permanent, expression of recombinant genes in the joint. Persistent as opposed to stable expression is desirable to

enable adjustments in the pharmacological dose of the recombinant gene product as the disease evolves over time.

Formulations for Gene Delivery into Cells of the Joint

Initial experiments used DNA in formulations for gene transfer into cells of the joint. This DNA is taken up by synovial cells during the process of these cells continually resorbing and remodeling the synovial fluid by secretion and pinocytosis. Gene delivery is enhanced by packaging DNA into particles using cationic lipids, hydrophilic (cationic) polymers, or DNA vectors condensed with polycations which enhance the entry of DNA vectors into contacted cells. Formulations may further enhance entry of DNA vectors into the body of the cell by incorporating elements capable of enhancing endosomal release such as certain surface proteins from adenovirus, influenza virus hemagglutinin, synthetic GALA peptide, or bacterial toxins. Formulations may further enhance entry of DNA vectors into the cell by incorporating elements capable of binding to receptors on the surface of cells in the joint and enhancing uptake and expression. Alternatively, particulate DNA complexed with polycations can be efficient substrates for phagocytosis by monocytes or other inflammatory cells. Furthermore, particles containing DNA vectors which are capable of extravasating into the inflamed joint can be used for gene transfer into the cells of the joint. One skilled in the art will recognize that the above formulations can also be used with other tissues as well.

Induction of "Steroid Response" by Gene Transfer of Steroid Receptors into Cells of the Joint

Current therapy for severe arthritis involves the administration of pharmacological agents including steroids to depress the inflammatory response. Steroids can be administered systemically or locally by direct injection into the joint space.

Steroids normally function by binding to receptors within the cytoplasm of cells. Formation of the steroid-receptor complex changes the structure of the receptor so that it becomes capable of translocating to the nucleus and binding to specific sequences within the genome of the cell and altering the expression of specific genes. Genetic modifications of the steroid receptor can be made which enable this receptor to bind non-natural steroids. Other modifications can be made to create a mutated steroid receptor which is "constitutively active" meaning that it is capable of binding to DNA and regulating gene expression in the absence of steroid in the same way that the natural steroid receptor regulates gene expression after treatment with natural or synthetic steroids.

Of particular importance is the effect of glucocorticoid steroids such as cortisone, hydrocortisone, prednisone, or dexamethasone which are effective drugs available for the treatment of arthritis. One approach to treating arthritis is to introduce a vector in which the nucleic acid cassette expresses a genetically modified steroid receptor into cells of the joint, e.g., a genetically modified steroid receptor which mimics the effect of glucocorticoid but does not require the presence of glucocorticoid for effect. This is achieved by expression of a fusion receptor protein discussed above or other mutated glucocorticoid receptors such as ones which are constitutively active within cells of the joint. This induces the therapeutic effects of steroids without the systemic toxicity of these drugs.

Alternatively, construction of a steroid receptor which is activated by a novel, normally-inert steroid enables the use of drugs which would affect only cells taking up this receptor. These strategies obtain a therapeutic effect from steroids on arthritis without the profound systemic complications associated with these drugs. Of particular importance is the ability to target these genes differentially to specific cell types (for

example synovial cells versus lymphocytes) to affect the activity of these cells.

The steroid receptor family of gene regulatory proteins is an ideal set of such molecules. These proteins are ligand activated transcription factors whose ligands can range from steroids to retinoic acid, fatty acids, vitamins, thyroid hormones and other presently unidentified small molecules. These compounds bind to receptors and either activate or repress transcription.

The preferred receptor of the present invention is modification of the glucocorticoid receptor, i.e., the fusion protein receptor. These receptors can be modified to allow them to bind various ligands whose structure differs from naturally occurring ligands. For example, small C-terminal alterations in amino acid sequence, including truncation, result in altered affinity of ligand binding to the progesterone receptor. By screening receptor mutants, receptors can be customized to respond to ligands which do not activate the host cell endogenous receptors.

A person having ordinary skill in the art will recognize, however, that various mutations, for example, a shorter deletion of carboxy terminal amino acids, will be necessary to create useful mutants of certain steroid hormone receptor proteins. Steroid hormone receptors which may be mutated are any of those receptors which comprise the steroid hormone receptor superfamily, such as receptors including the estrogen, progesterone, glucocorticoid- α , glucocorticoid- β , mineral corticoid, androgen, thyroid hormone, retinoic acid, and Vitamin D3 receptors.

Direct DNA Delivery to Muscle

Diseases that result in abnormal muscle development, due to many different reasons can be treated using the above modified glucocorticoid receptors. These diseases can be treated by using the direct delivery of genes

encoding for the mutated glucocorticoid receptor of the present invention resulting in the production of mutated receptor gene product. Genes which can be repressed or activated have been outlined in detail above.

5 Direct DNA Delivery to the Lungs

Current therapy for severe asthma involves the administration of pharmacological agents including steroids to inhibit the asthma response. Steroids can be administered systemically or locally by direct instillation or
10 delivery into the lungs.

Of particular importance is the effect of glucocorticoid steroids such as cortisone, hydrocortisone, prednisone, or dexamethasone which are the most important-effective drugs available for the treatment of asthma.
15 One approach to treating asthma is to introduce a vector in which the nucleic acid cassette expresses a genetically modified steroid receptor into cells of the lungs, e.g., a genetically modified steroid receptor which mimics the effect of glucocorticoid but does not require the presence
20 of glucocorticoid for effect. This is achieved by expression of the fusion proteins discussed above or other mutated glucocorticoid receptors such as ones which are constitutively active within cells of the lungs. This induces the therapeutic effects of steroids without the
25 systemic toxicity of these drugs.

Alternatively, construction of a steroid receptor which is activated by a novel, normally-inert steroid enables the use of drugs which would affect only cells taking up this receptor. These strategies obtain a
30 therapeutic effect from steroids on asthma without the profound systemic complications associated with these drugs. Of particular importance is the ability to target these genes differentially to specific cell types (for example alveoli of the lungs) to affect the activity of
35 these cells.

The steroid receptor family of gene regulatory proteins is an ideal set of such molecules. These proteins are ligand-activated transcription factors whose ligands can range from steroids to retinoids, fatty acids, vitamins, thyroid hormones, and other presently unidentified small molecules. These compounds bind to receptors and either up-regulate or down-regulate transcription.

The preferred receptor of the present invention is the modified glucocorticoid receptor. These receptors can be modified to allow them to bind various ligands whose structure differs from naturally occurring ligands. For example, small C-terminal alterations in amino acid sequence, including truncation, result in altered affinity of the ligand and altered function. By screening receptor mutants, receptors can be customized to respond to ligands which do not activate the host cells own receptors.

A person having ordinary skill in the art will recognize, however, that various mutations, for example, a shorter deletion of carboxy terminal amino acids, will be necessary to create useful mutants of certain steroid hormone receptor proteins. Steroid hormone receptors which may be mutated are any of those receptors which comprise the steroid hormone receptor superfamily, such as receptors including the estrogen, progesterone, glucocorticoid- α , glucocorticoid- β , mineral corticoid, androgen, thyroid hormone, retinoic acid, and Vitamin D3 receptors.

Examples

While the present invention is disclosed by reference to the details for the following examples, it is to be understood that this disclosure is intended in an illustrative rather than limiting sense, as it is contemplated that modifications will readily occur to those skilled in the art, within the spirit of the invention and the scope of the appended claims.

Mutagenesis and Characterization of the Ligand Binding
Domain of Human Progesterone Receptor

Example 1

Yeast Strain

5 The *Saccharomyces cerevisiae* strain BJ3505 (MAT α ,
pep4:HIS3, prb1- Δ 1.6R, his3 Δ 200, lys2-801, trp1- Δ 101,
ura3-52, gal2, (CUP1)) was used (Yeast Genetic Stock
Center, Berkeley, CA). All yeast transformations were
carried out following the lithium acetate transformation
10 protocol (Ito, et al., *J. Bacteriol.* 153:163-168, 1983).

 The PCR reactions were carried out using YEpHPR-B DNA
template (a YEp52AGSA-derived yeast expression plasmid
containing the cDNA of hPR form-B (Misrahi, et al.,
Biochem. Bioph. Res. Comm. 143:740-748, 1987) inserted
15 downstream of the yeast methallothionein-CUP1 promoter)
and using three different sets of primers. In order to
decrease the fidelity of the second strand polymerization
reaction, buffer conditions of 1.5 mM MgCl₂, 0.1 mM dNTPs
and pH 8.2 were used. About 2000 primary transformants
20 were obtained from each region-specific library.

Example 2

Yeast Mutant Screening

 Colonies of each library of hPR molecules mutated in
specific subregions were pooled, large amounts of DNA were
25 prepared and used to transform yeast cells carrying the
reporter plasmid YRpPC3GS+, which contains two GRE/PRE
elements upstream of the CYC1 promoter linked to the Lac-Z
gene of *E. coli* (Mak, et al., *J. Biol. Chem.* 265:20085-
20086, 1989). The transformed cells were plated on 1.5%
30 agar plates containing 2% glucose, 0.5% casamino acids (5%
stock solution of casamino acids is always autoclaved
before use to destroy tryptophan), 6.7 g/l yeast nitrogen
base (without amino acids) and 100 μ M CuSO₄ (CAA/Cu
plates) and grown for 2 days at 30°C. These colonies were
35 then replica-plated on CAA/Cu plates containing 0.16 g/l
of 5-bromo-4-chloro-3-indolyl- β -D-galactoside (X-Gal, an

indicator of β -galactosidase activity) with or without the hormones as indicated in Fig. 1 and allowed to grow for one day at 30°C, then two days at room temperature in the dark.

5 Example 3

Growth of Yeast Culture for In Vitro Assay

Saccharomyces cerevisiae cells containing YEphPRB and the reporter plasmid were grown overnight at 30°C in minimal media containing 2% glucose. The cells were
10 subcultured in fresh medium and allowed to grow until early mid-log phase ($\text{O.D.}_{600\text{nm}}=1.0$). Induction of receptor was initiated by the addition of 100 μM copper sulfate to the culture. Cells were harvested by centrifugation at 1,500 $\times g$ for 10 minutes and resuspended in the appropriate
15 buffer. This and all subsequent steps of analysis of the yeast extracts were done at 4°C.

Example 4

Transcription Assay

Yeast cells containing the reporter and expression
20 plasmids were grown overnight as described above in Example 3 in the presence of 100 μM copper sulfate. When the cell density reached $\text{O.D.}_{600\text{nm}}=1.0$, hormones were added to the cultures. After a 4 hour incubation, yeast extracts were prepared and assayed for β -galactosidase
25 activity as described previously (Miller, J. M. Miller ed., 352-355 (1972)).

Generally, reporters useful in the present invention are any which allow for appropriate measurement of transcription levels. Preferable reporter systems include
30 reporter vectors comprised of the yeast iso-1-cytochrome C proximal promoter element fused to a structural gene, wherein said structural gene is selected from the group consisting of β -galactosidase, galactokinase and URA3. More preferably, the vector is comprised of an insertion
35 site for a receptor response element. The vectors which

include β -galactokinase as an indicator of transcriptional activity are derived from the parent vector PC2 while the vectors which include galactokinase are derived from YCpR1 vector. Preferably, the structural genes originate from
5 *E. coli*.

Example 5

Western Immunoblotting

Yeast cells were grown as discussed above for the transcription assay. Yeast extracts for Western blot
10 analysis were prepared by resuspending the cell pellet in TEDG+salts. The cell suspension was mixed with an equal volume of glass beads and disrupted by vortexing in a microcentrifuge tube. The homogenate was centrifuged at 12,000 x g for 10 minutes. The supernatant was collected
15 and the protein concentration was estimated using bovine serum albumin as standard. Yeast extracts were resolved on a 0.1% sodium dodecyl sulfate-7% polyacrylamide gel and transferred to Immobilon membrane as described previously (McDonnell, et al., *Mol. Cell. Biol.* 9:3517-3523, 1989).
20 Solid phase radioimmunoassay was performed using a monoclonal antibody (JZB39) directed against the N-terminal domain of A and B forms of hPR.

Example 6

Hormone Binding Competition Assays

25 Induction of PR synthesis was initiated by the addition of 100 μ M CuSO₄ to the culture and incubation was continued for 6 hours. The cell pellet was resuspended in TESH buffer containing 1 μ g/ml leupeptin, 10 μ g/ml PMSF and 10 μ g/ml pepstatin. The cell suspension was mixed
30 with an equal volume of glass beads (0.5 mm; B. Braun Instruments) and disrupted by vortexing in a microcentrifuge tube. The homogenate was centrifuged at 12,000 x g for 10 minutes and the supernatant was further centrifuged at 100,000 x g for 30 minutes to obtain a cytosol
35 fraction. Diluted yeast extracts (200 μ l) containing 100

µg of total protein were incubated overnight at 4°C with [³H]ligand in the absence (total binding) or presence (non-specific binding) of a 100-fold excess of unlabeled ligand. Bound and free steroids were separated by addition of 500 µl of dextran-coated charcoal suspension (0.5% Norit A, 0.05% dextran, 10 mM Tris HCl, pH 7.4 and 1 mM EDTA). Specific binding was determined by subtracting nonspecific from total binding. Scatchard analysis was carried out as described previously by Mak, et al., *J. Biol. Chem.* 264:21613:21618 (1989).

Example 7

Site-Directed Mutagenesis

Mutants YEphPR-B879 and YEphPR-B891 were prepared following the procedure described by Dobson, et al., *J. Biol. Chem.* 264:4207-4211 (1989). CJ236 cells were infected with mpPR90 (an M13 plasmid containing hPR cDNA). The resulting uridine-containing single-stranded DNA was annealed to 20-mer oligonucleotides containing a TGA stop codon corresponding to amino acids 880 and 892, respectively.

Example 8

Construction of Mammalian Expression Vectors

The mammalian expression vector phPR-B contains the SV40 enhancer sequence upstream of the human growth hormone promoter linked to the hPR-B cDNA. This vector was digested with Sall and EcoR1. The 6.1kb fragment (containing the vector sequences and the 5'-1.5 kb of the hPR) was gel-purified and ligated to the 2.1 kb fragment of YEphPR-B891 (containing the 3'-end of the receptor) previously cut with Sall and EcoR1. The resulting plasmid, phPR-B891, encodes a 42 amino acid truncated version of hPR form B.

Example 9Mammalian Cell Transient Transfections and CAT-Assays

Five micrograms of chloramphenicol acetyltransferase (CAT) reporter plasmid, containing two copies of a PRE/GRE from the tyrosine amino transferase gene linked to the thymidine kinase promoter (PRETKCAT), were used in transient cotransfection experiments together with 5 µg of wild type or mutant receptor DNAs. Transient cotransfections and CAT-assays were performed as described by Tsai et al., Cell 57:443-448 (1989).

Example 10Mutagenesis of the Hormone Binding Domain of hPR-B

In order to characterize amino acids within the hPR HBD which are critical for ligand binding and hormone-dependent transactivation, libraries of mutated hPR molecules were created and the mutants introduced into a reconstituted progesterone-responsive transcription system in yeast. This system allowed the screening of large numbers of mutant clones and the direct, visual identification of phenotypes.

Unique restriction sites for NaeI, AvrII and EcoNI were created in the cDNA of hPR, obtaining three cassettes of 396, 209 and 400 nucleotides (regions 1, 2 and 3, respectively). For PCR mutagenesis three sets of primers (16 + 7 for region 1, 5 + 4 for region 2 and 6 + 13 for region 3) were used in the polymerization reaction using YEphPR-B as DNA template. The fragments obtained after PCR were digested with the appropriate enzymes, gel-purified and ligated into the parental plasmid YEphPR-B. Ligation mixes were used to transform bacterial cells and to obtain libraries of hPR molecules randomly point-mutated in the HBD. 5 µg of DNA were used from each library to transform yeast cells carrying the reporter plasmid YRpPC3GS+ and transformants were selected for tryptophan and uracil auxotrophy on CAA plates containing 100 µM CuSO₄. These were then replicated on CAA plates

containing the hormones. The screening for "up-mutations" allowed identification of receptor mutants with hormone-independent transcriptional activity, or increased affinity for the ligand (these clones should remain blue when
5 grown with 100-fold less hormone), or with an altered response to RU486 or a glucocorticoid analogue. In the "down-mutation" screening, receptor mutants that were transcriptionally inactive in the presence of the ligand were detected.

10 Because of the nature of the method used to generate the mutated DNA templates, it was necessary, firstly, to determine the quality of the libraries obtained. This was assessed by estimating the number of null-mutations generated by mutagenesis. We estimated the frequency of
15 occurrence of transcriptionally inactive receptors (white colonies) compared to the total number of colonies. This frequency was about 7%.

The primary transformants were replica-plated onto plates containing the antiprogestin RU486. The wild type
20 receptor is not activated by this hormone (Fig. 1). Using this screening strategy, a single colony was identified that displayed considerable transcriptional activity in response to the antihormone. Interestingly, the same colony did not display transcriptional activity when
25 replica-plated in the presence of progesterone. The colony was purified and the phenotype was confirmed. Eviction of the expression vector from the clone, followed by reintroduction of the unmutated receptor, demonstrated that the phenotype was indeed related to the expression
30 vector and was not the result of a secondary mutation. In addition, the mutated plasmid called UP-1, was rescued from yeast by passage through *E.coli* (as described in Ward, *Nucl. Acids Res.* 18:5319 (1990)) and purified. This DNA was then reintroduced into yeast that contained only
35 the reporter plasmid. As expected, the mutant phenotype was stable and related directly to the receptor expression plasmid.

Example 11Characterization of the UP-1 Mutant

The plate assays used to identify the receptor mutants are qualitative in nature. To further
5 characterize the properties of UP-1, the activity of the receptor mutants was compared with that of the wild type receptor in a transcription assay. In this method, yeast cells transformed with either the wild type or the mutant receptor and a progesterone responsive reporter were grown
10 overnight in the presence of 100 μ M CuSO₄. When the cells had reached an O.D._{600nm} of 1.0, they were supplemented with progesterone or RU486 and harvested by centrifugation after four hours. The β -galactosidase activity in the cell cytosol was then measured.

15 With reference to Figure 2, panel (A), when assayed with the wild type receptor, 1 μ M RU486 is a weak inducer of transcription, whereas progesterone caused a greater than 60-fold induction of transcription at 1 μ M. However, this situation was reversed when the mutant was analyzed.
20 In this case, RU486 was an extremely potent activator, whereas progesterone was ineffective. Interestingly, the activity achieved by the mutant in the presence of RU486 was of the same order of magnitude as that of the wild type assayed in the presence of progesterone. This
25 reversal in specificity clearly indicates that the mechanism by which these ligands interact with the receptor is basically different.

Figure 2 shows the DNA and amino acid sequences of the wild type and mutant DNAs. The cytosine at position
30 2636 was missing in the mutant DNA, therefore, a shifted reading frame was created and a stop codon was generated 36 nucleotides downstream of the C-2636 deletion. A schematic structure of the wild type and UP-1 receptors is also presented with a depiction of the 12 C-terminal amino
35 acids unique to the mutant receptor. Conserved and structurally similar amino acids are marked by an apostrophe and asterisk, respectively.

DNA sequence analysis of UP-1 identified a single nucleotide deletion at base 2636 (Fig. 2B). This mutation results in a shift of the reading frame which generates a stop codon 36 nucleotides downstream. As a result, the wild type receptor is truncated by 54 authentic amino acids and 12 novel amino acids are added at the C-terminus.

Example 12

Western Analysis of the Mutant Human Progesterone Receptor

Figure 3 shows a western analysis of mutant hPR. Yeast cells carrying the reporter plasmid and wild type (yhPR-B or mutant (UP-1) hPR were grown overnight in CAA medium with (lanes 3 to 5 and 7 to 9) or without (lanes 2 and 6) 100 μ M CuSO_4 . 1 μ M progesterone or 1 μ M RU486 were added as indicated and cells were grown for another 4 hours. Yeast extracts were prepared as described above. 50 μ g of protein extract were run on a 0.1% SDS-7% polyacrylamide gel. 50 μ g of a T47D nuclear extract containing the A and B forms of hPR were also loaded (lane 1) as a positive control. The positions of molecular weight markers are indicated.

A Western immunoblot analysis of UP-1 and wild type receptors was performed in order to verify that the mutant receptor was synthesized as predicted from its DNA sequence and to eliminate the possibility that some major degradation products were responsible for the mutant phenotype. As shown in Fig. 3, the mutant receptor migrated faster in the gel, confirming the molecular weight predicted by DNA sequencing. The wild type receptor (yhPR-B) ran as a 114 kDa protein, while the mutant receptor was 5kDa smaller (compare lanes 2 and 3 with 6 and 7). The addition of 100 μ M CuSO_4 to the cell cultures increased synthesis of both the wild type and mutant hPR to the same extent. No major degradation products were detected. In the presence of progesterone and RU486, yhPR-B bands were upshifted due to hormone-induced phos-

phorylation of the receptor. In contrast, RU486 induced upshifting of wild type PR to a lesser extent (lanes 4 and 5). For the UP-1 mutant this hormone-dependent upshifting was seen upon treatment with RU486 (lanes 8 and 9). Thus, the C-terminus of PR may be responsible for the inactivity of RU486. Consequently, removal of this sequence would enable RU486 to become an agonist.

Example 13

Hormone Binding Analysis

Figure 4 shows the transcriptional activity and hormone binding analysis of wild type and mutant hPR constructs. The hPR constructs are reported to the left side together with a schematic representation of the receptor molecules. Yeast cells were grown in the presence of 100 μ M CuSO₄. Transcriptional analysis was done as described above. Experiments were done in triplicate and transcriptional activities were normalized with respect to protein. Hormone binding assays were performed in the presence of 20 nM [³H] progesterone or 20 nM [³H] RU486.

A saturation binding analysis of the UP-1 mutant receptor was performed in order to determine if its affinity for RU486 and progesterone was altered. Scatchard analysis of the binding data demonstrated that both the wild type and mutant receptors had a similar affinity for RU486 of 4 and 3 nM, respectively. As seen in Figure 4, the mutant receptor molecule had lost the ability to bind progesterone. Thus, the amino acid contacts for progesterone and RU486 with hPR are different.

Example 14

Generation of Deletion Mutants of hPR-B

As shown in Fig. 2B, DNA sequencing revealed that the frameshift mutation in the UP-1 clone created a double mutation in the receptor protein. That is, a modified C-

terminal amino acid sequence and a 42 amino acid truncation. In order to identify which mutation was ultimately responsible for the observed phenotype, two new receptor mutants were constructed *in vitro*: YEphPR-B879, containing
5 a stop codon corresponding to amino acid 880, and YEphPR-B891, containing a stop codon at amino acid 892. Hormone binding data (see Fig.4) demonstrated that both of these truncated receptors could bind RU486 but not progesterone. When examined *in vivo*, both mutant receptors activated
10 transcription in the presence of RU486 to levels comparable to those of the mutant UP-1 generated in yeast. As expected, both mutants were inactive in the presence of progesterone. Thus, the observed phenotype was not due to second site mutations in the UP-1 molecule. Also, 12
15 additional amino acids, from 880 to 891, were not responsible for the mutant activity. In addition, it is clear the C-terminal 42 amino acids are required for progesterone to bind to the receptor while the last 54 amino acids are unnecessary for RU486 binding. Thus, the antagonist
20 is contacting different amino acids in the native receptor molecule and may induce a distinct receptor conformation relative to agonists.

In addition to the above deletion mutations, other deletions in the C-terminal amino acid sequence have
25 provided binding activity with RU486 and not with progesterone. Such deletions include: (1) a 16 amino acid deletion leaving amino acids 1-917 of the progesterone receptor; and (2) a 13 amino acid deletion leaving amino acids 1-920 of the progesterone receptor. Use of
30 the receptor binding region with TATA-CAT expression in transient transfection assays showed CAT expression with the 16 amino acid deletion, *i.e.*, amino acids 640-917, and the 13 amino acid deletion, *i.e.*, amino acids 640-920.

Example 15Steroid Specificity for Activation of Transcription of the UP-1 Mutant

Figure 5 shows the specificity of the transcriptional
5 activity of the mutant hPR. In panel (A), wild type and
UP-1 mutant receptor transcriptional activities were
assayed in the presence of different concentrations of
progesterone, RU486, Org31806 and Org31376 as indicated.

A transcription assay was performed using two
10 synthetic antagonists, Org31806 and Org31376, which are
potent antiprogestins. As shown in Fig. 5A, the mutant
receptor was activated by both of these compounds. The
curve of the concentration-dependent activity was similar
to that obtained with RU486, suggesting that the affinity
15 of these two antagonists for the mutant receptor is
similar to that of RU486. When assayed with the wild type
receptor, these compounds had minimal transcriptional
activity and behaved like partial agonists (3-10% of
progesterone activity) only at concentrations of 1 μ M, as
20 does RU486. Thus, the inhibitory effect of the C-terminus
of hPR extends to other receptor antagonists.

In panel (B), transcriptional activities of wild type
and UP-1 mutant receptors were assayed in the presence of
1 μ M progesterone (P), RU486 (RU), R5020 (R), dexametha-
25 sone (D), cortisol (C), estradiol (E), tamoxifen (TX) or
nafoxidine (N) (see Fig.5B). The synthetic agonist R5020
had no effect on the UP-1 mutant, suggesting that agon-
ists, such as progesterone and R5020, require the C-
terminus of the native receptor for binding and conse-
30 quently fail to recognize the truncated UP-1 receptor.
Other steroids known to enter yeast cells, such as estra-
diol, the antiestrogens tamoxifen and nafoxidine, dexa-
methasone and cortisol, might possibly activate the
mutated receptor. All steroids tested were found to be
35 inactive with either the wild type or mutant receptor.
Thus, the activation of the mutant receptor is specific to
antiprogestins.

Example 16Transcriptional Activity of Mutant Receptors in Mammalian Cells

Figure 6 shows the transient transfection of mutant hPR into mammalian cells. In panel (A), HeLa cells were transiently transfected with phPR-B and pHPR-B891 receptors together with PRETKCAT receptor plasmid using the polybrene method of transfection as described (Tsai, et al. 1989). Cells were grown with or without 100 nM progesterone or RU486 for 48 hours prior to harvesting. CAT assays were performed as described above. In panel (B), CV-1 cells were transiently transfected as in (A).

With reference to Figure 6, mutant receptor activity was assayed in both human endometrial HeLa cells and monkey kidney CV-1 fibroblasts. A mutant, phPR-891, was constructed by replacing the full-length PR insert of phPR-B vector with the truncated PR cDNA of YEphPR-B891. The resulting receptor mutant, phPR-B891, is a 42 amino acid truncation of hPR-B form. Mutant 891 and wild type receptors were transfected into HeLa cells together with the PRETKCAT reporter plasmid, which contains two copies of a GRE/PRE element.

As expected, wild type PR activated transcription of the CAT gene reporter in the presence of 10^{-7} M progesterone (Fig. 6A). Although basal transcription level was high, a 3- to 4-fold induction of transcription was detected when progesterone was added to the media. In contrast, no induction occurred in the presence of RU486. The high basal level of transcription detected in these experiments may mask or alter an RU486 effect on wild type hPR.

On the other hand, an induction of CAT activity was observed when the 891 mutant was incubated in the presence of 10^{-7} M RU486 (Fig. 6A). The same concentration of progesterone had no activity.

Cell-type specific factors can influence the activity of the transactivating domains of steroid receptors. In order to evaluate this possibility, wild type and mutant

receptors were transfected into CV-1 cells. Similar results were obtained, i.e., progesterone activated the wild type receptor while RU486 activated 891 mutant receptor (Fig. 6B).

- 5 The protein synthesized from phPR-B891 plasmid was of the correct molecular weight in mammalian cells. The mutant receptor was transfected into COSM6 cells. Western analysis on cell extracts showed that the 891 mutant was synthesized, as expected, as a protein of 109 kDa, which
10 corresponds to a protein 42 amino acids shorter than the wild type hPR. Thus, RU486 acts as an agonist of the truncated B-receptor in a yeast reconstituted system and also in mammalian cells. The mechanism of transactivation does not require the C-terminal tail of the mutant recep-
15 tor and is conserved between the three species tested.

Example 17

Construction of poly-glutamine stretch insertion into the LBD

- 20 The poly-glutamine stretch containing multiple repeats of CAG was constructed by a method developed by S. Rusconi (Seipel et al., *Nucl. Acid Res.* 21:5609-5615) utilizing multimerization of DNA fragment (BsaI and BbsI digested) coding glutamine repeats leading to poly-Q_n. Plasmid pBluscript-KS(II) was digested with Acc65I and
25 SacI, the linearized vector was gel purified and ligated with the annealed oligonucleotide pair R3/R4 to create plasmid pPAP. The oligonucleotide sequence for R3 (upper strand) is: 5'-GTACGTTTAAACGCGGCGCGCCGTCGACCTGCAGAAGCTTACT
AGTGGTACCCCATGGAGATCTGGATCCGAAT TCACGCGTTCTAGATTAATTAAGC-
30 3' (Seq. ID No. 2) and the sequence for R4 (lower strand) is: 5'-GGCCGCTTAATTAATCTAGAACGCGTGAATTCGGATCCAGATCTCCATG
GGGTACCACTAGTAAGCTTCTGCAGGTCGACGGCGCGCCGCGTTTAAAC-3' (Seq. ID No. 3).

- 35 The following restriction sites are incorporated into pPAP as the multiple cloning sites (from T3 to T7): PmeI, AscI, SalI, PstI, HindIII, SpeI, Acc65I, NcoI, BglII,

BamHI, EcoRI, MluI, XbaI, PacI, NotI, SacI. Oligonucleotides coding for 10 glutamines were annealed and subcloned into the BglII and BamHI site of plasmid pPAP. The sequence for the upper and lower strand oligonucleotide are, 10QU 5'-GATCTCGGTCTCCAACAGCAACAGCAACAGCAACAGCAACAGGCTCTTCTG-3' (Seq. ID No. 4) and 10QL: 5'-GATCCAGAAGACCCTGTTGCTGTTGCTGTTGCTGTTGCTGTTGCTGTTGAGACCGA-3' (Seq. ID No. 5), respectively. The insert was confirmed by restriction digestion and sequencing.

10 The plasmid with 10Q insert (pPAP-10Q) was digested
with BsaI and BbsI (New England Biolab) overnight and
precipitated. One tenth of the precipitated DNA (contain-
ing both vector and fragment) was religated to create
15 plasmid pPAP-18Q. Each ligation step results in pAP-2(n-
1)Q from the previous vector pPAP-nQ. In this way various
expansion of poly-Q was achieved and resulting plasmids
pPAP-34Q, pPAP-66Q and pPAP132Q were created and confirmed
by sequencing. The BglII and BamHI fragment (coding for
poly-Q stretch) from these plasmids were purified and
20 cloned into BglII site of pRSV-GLVP to generate GLVP with
various poly-Q insert at the N-terminus. These GLVP-nQ
were reinserted into the pCEP4 vector creating pCEP4-GLVP-
nQ.

Lengthening the C-terminal ligand binding domain from 25 879 to 914 (Figure 17), gradually increased RU486 induced activation of target gene expression. Importantly, these mutants responded specifically to RU486, but not to the progesterone agonist R5020. Further extension of the C-terminal LBD beyond aa 914 resulted in a decrease of GLVP 30 response to RU486.

Construction, Characterization and Analysis of Mutant Human GR-PR Fusion Protein Receptors

Example 18

Plasmid Construction

35 A mutated human Progesterone Receptor was constructed
and characterized as discussed above. Mutagenesis of the

ligand binding domain of the human PR was carried out under the same procedures outlined above. Characterization of the mutant progesterone receptor identified a single nucleotide deletion at base 2636. This mutation
5 resulted in a shift of the reading frame which generates a stop codon 36 nucleotides downstream. As a result, the wild type receptor is truncated by 54 authentic amino acids and 12 novel amino acids are added at the c-terminus. The 42 amino acid truncation to the c-terminus
10 was capable of binding RU486 and characterized as discussed above.

Plasmid DNA encoding the GR-PR fusion protein receptor and the wild type GR were constructed as follows. Each insertional mutant was digested with the restriction
15 enzymes BamH1 and XhoI, which flanked the 3' side of the SV40 polyadenylation signal. The resulting fragments were isolated from an agarose gel. The large fragment of the insertional mutant containing the amino-terminal coding portion of the GR, i.e., the transregulatory and DNA
20 binding region, and the bulk of the plasmid were ligated with the small fragment of another insertional mutant containing the carboxyl terminal coding sequence of the hPR deletion mutant prepared above. The resulting plasmids carrying the deletion in the hPR ligand binding
25 domain were sequenced to ensure the integrity of the GR-PR mutant constructs.

In addition, plasmid DNA encoding a mutated rat or human GR and the wild type rat or human GR were also constructed. The plasmids for rat pGR0385 (or prCS1.C) and
30 its wild type pGR0384 were constructed using the above methods. Details regarding construction, mutation and characterization of the above plasmid can be found in Lanz and Rusconi, *Endocrinology* 135:2183-2195 (1994), all of which is hereby incorporated by reference, including
35 drawings. Characterization of the rat and human mutant GR identified a double point mutation in the ligand binding domain. In the rat construct, amino acids 770, 771, meth-

onine and leucine, were substituted with alanine and alanine. Amino acids 780 and 781 were deleted. In the human constructs, amino acids 762 and 763 were deleted. Amino acids 752 and 753 were substituted with alanines.

5 Both the substitution and deletion changes were at the carboxyl terminus portion of the rat or human GR ligand binding domain. The insertional mutant was digested with the restriction enzymes BamH1 and Xho1, which flank the 3' side of the SV40 polyadenylation signal and the resulting

10 fragment was isolated from agarose gel. The large fragment of one insertional mutant containing the amino-terminal coding portion of the rat or human GR and the bulk of the plasmid were ligated with the small fragment of another insertional mutant containing the carboxy-

15 terminal coding sequences of the mutated ligand binding domain. The resulting plasmids carrying the deletion in the ligand binding domain were sequenced to ensure the integrity of the rat or human GR mutants.

In addition, the above procedures were also used to

20 construct plasmid DNA encoding a GR mutant with a constitutively active receptor, i.e., pGR0403R (Figures 9 and 10). The insertional mutant was digested with the appropriate restriction enzyme. The resulting fragments were isolated from agarose gel. The large fragment of the

25 insertional mutant containing the amino-terminal coding portion of the GR, i.e., the transregulatory domains and DNA binding domains, and the bulk of the plasmid were ligated with the small fragment of another insertional mutant containing the mutated GR ligand binding domain.

30 The resulting plasmid was sequenced (Figure 9) to ensure integrity of the mutant construct.

Example 19

Cell Culture, Transfection and Assay of CAT and Luciferase Activities

35 CV-1 cells were maintained at 37°C in Dulbecco modified Eagle medium containing 10% fetal bovine serum

("FBS") in a humidified atmosphere containing 5% CO₂. Cells were transfected using the commercially available cationic agent lipofectamine. Briefly, DNA was mixed with the lipofectamine reagent and added to cells. After 5 hours, the DNA mix was removed and replaced with growth medium containing 10% FBS and cells were returned to an atmosphere containing 5% CO₂. Eighteen hours later, cells were treated with steroids at various concentrations for approximately 24 hours, then harvested.

10 In this method, the CV1 cells are transformed with either the wild-type receptor or the mutant receptor and a glucocorticoid responsive reporter construct. To measure transcriptional activation, a CAT reporter containing two synthetic GRE's and a TATA box was used. To measure
15 transcriptional repression, two constructs were used. The first contains two copies of the binding site for the inflammation-inducible transcription factor AP-1, following by the thymidine kinase (tk) promoter, linked to CAT. The second contains two copies of the binding site for the
20 inflammation-inducible transcription factor NF κ -B, followed by a TATA box, linked to the luciferase gene. CAT expression was quantified using an ELISA assay following the manufacturer's recommended procedure. Luciferase activity was measured using a commercially-available luciferase
25 assay following the manufacturer's recommended procedure.

Example 20

In vitro Transfections Using CV1 Cells

The GR-PR fusion protein receptor and the mutant rat GR were tested for biological activity through in vitro
30 transfection into CV1 cells. As controls vectors expressing the wild type human GR and the wild type rat GR were used. Results from these experiments demonstrate that the wild type human and wild type rat GR are transcriptionally activated in response to dexamethasone
35 and minimally by RU486. In contrast, the mutant rat GR (CS1.CD) is transcriptionally activated by RU486 and not

by dexamethasone. Similarly, the GR-PR fusion protein receptor is also activated by RU486 and not by dexamethasone. Figure 11 illustrates the amount of CAT protein produced in response to the particular ligand.

5 Example 21

In vitro Transcriptional Repression Studies

The transcriptional repression mediated by the mutant rat GR and human GR-PR construct were examined. The amount of CAT protein produced under the transcriptional
10 control of synthetic activation elements was determined.

Specifically two reporters were examined TRE2tkCAT, which contains AP-1 fused to the thymidine kinase promoter linked to CAT. The second reporter used was NF κ -B-luc plasmid, which contains 2 NF κ -B binding sites fused to
15 luciferase. These promoters contain inflammation-inducible promoters, and were used to evaluate the ability of the wild-type and mutant GR constructs to repress transcription.

Cells were transfected into CV1 cells along with
20 either the wild type rat or human GR or the mutant rat (CS1.CD) or human GR. Cells pretreated with dex or RU486 to allow binding to the steroid receptor, were then stimulated with phorbol ester TPA to activate AP-1 and NF κ -B. Companion cells were not stimulated with TPA, and
25 control cells also received neither dex nor RU486.

The results demonstrate that RU486 treatment resulted in a decrease in the level of CAT protein and luciferase activity in CSI.CD transfected cells. Dex treatment had no effect on CAT levels or luciferase. These results were
30 not expected since dex does not bind to the ligand binding domain of the mutant rat GR CSI.CD or human GR. In cells transfected with the wild type GR both dex and RU486 caused a decrease in the level of CAT protein and luciferase activity. Such results are not unexpected
35 because the wild type GR binds both dex and RU486.

RU486 acts through the mutated GR to repress transcription of AP1 driven genes. Since AP-1 and NF κ -B drive expression of pro-inflammatory genes, and RU486 acts through mutant or represses transcription of the AP-1 and
5 NF κ -B driven genes, there was mediation of the anti-inflammation.

Example 22

Mutant GR Expression and Detection

Three antibodies were obtained and used to recognize
10 recombinant partially purified GR in a Western blot analysis. Studies were performed to detect wild type GR and mutant GR protein from transfected cells or GR from rat synovial tissue using the above antibodies.

The antibodies also were able to detect human GR
15 obtained from HeLa cell extracts. Significant levels of GR were detected with as low as 200ug of whole cell extract. Immunoreactivity was also detected with synovial tissue, and antibodies are being prepared to distinguish between wild type and mutant GR proteins.

20 Example 23

Transactivation and Transrepression Studies

In addition to the experiments above, the vector with NF κ -B binding sites fused to the luciferase gene, was injected into synovial joints in rats and treated with and
25 without TNF- α . TNF- α is a cytokine which induces inflammation and promotes NF κ -B binding to its appropriate DNA sequences. With the DNA construct, TNF- α treatment results in an increase in transcription of TNF- α and exogenously-introduced luciferase gene. No luciferase
30 activity in synovial tissue is detected without plasmid transfection. Also, there is no luciferase activity in synovial tissue injected with plasmid in the absence of TNF. A six-fold increase in the level of luciferase occurred when tissue was exposed to 0.1 or 1nM TNF. This

serves as an easily detectable in vivo marker for wild-type or mutant GR function.

Construction, Characterization and Analysis of Double Point Mutations in the Ligand Binding Domain of GR

5 Example 24

Mutagenesis of the ligand binding domain of human GR

A plasmid was constructed containing the human GR cDNA with amino acids 752 and 753 changed to alanines and amino acids 762 and 763 deleted. This plasmid, pSTC-hGR-
10 CS1/CD, was constructed as follows. The wild type glucocorticoid hormone receptor plasmid was digested with the restriction enzymes NsiI and XbaI, which flank the region to be mutated. The resulting fragments were isolated from agarose gel. The smaller fragment was digested with the
15 restriction enzymes EcoRI and SspI, generating three fragments. The fragments were isolated from an agarose gel.

A synthetic fragment was synthesized: 5'-AAT TCC CCG AGG CGG CAG CTG AAA TCA TCA CCA ATC AGA TCT-3' (Seq. ID
20 No. 6) to replace the EcoRI-SspI fragment. The larger plasmid fragment, the NsiI-EcoRI fragment, the SspI-XbaI fragment and the synthetic EcoRI-SspI fragment were ligated together. The resulting plasmid carries the substitution and deletion as described above.

25 Example 25

Characterization of GR Mutants in the Ligand Binding Domain

To ensure the integrity of the mutation, the plasmid containing the mutant human GR was sequenced. Further
30 experiments, as discussed above, were done to characterize the mutant human GR. Western analysis and hormone binding as discussed above were performed to ensure character of the constructs, e.g., cell expression of the protein and steroid specificity for activation or repression of
35 transcription.

Example 26Transcriptional Activity of the Mutant Receptors in Mammalian Cells

LMTK⁺ cells were maintained at 37°C in Bulbecco's modified Eagle's medium containing 10% fetal Bovine serum ("FBS") in a humidified atmosphere containing 5% CO₂. Cells were transfected with the polybrene method described in Kawai et al., *Mol. Cell. Bio.* 4:91-1172 (1984), hereby incorporated by reference, including drawings. After a 25% glycerol shock in Hank's buffered saline solution ("HBSS"), the cells were washed twice with HBSS and medium was added containing hormones or solvent. The cells were cultured for 48 hours. Extracts were made by freeze-thawing. CAT activity was assayed with 25 µg protein and an incubation time of 16 hours. CAT activity assayed as described by Seed et al., *Gene* 67:271 (1988), hereby incorporated by reference, including drawings.

Construction, Characterization and Analysis of Constitutively Active Mutant GRExample 27Mutagenesis of the ligand binding domain of human GR

Deletion of the steroid ligand binding domain was prepared as follows. This deletion removed a large portion of the carboxyl-terminal portion of the protein eliminating all steroid binding properties. Using the procedures discussed above, the pGR0403R plasmid (Figures 9 and 10) was constructed. This mutation gave rise to a constitutively active receptor. This mutant was able to activate transcription of the CAT reporter gene in the presence or absence of glucocorticoid hormone. In addition, this mutant is also able to repress transcription of the NF_κ-B-luciferase construct.

Example 28Characterization of GR Mutants in the Ligand Binding Domain

To ensure the integrity of the mutation, the plasmid
5 containing the mutant human GR, pGR0403R (Figure 10) was
sequenced (Figure 9). Further experiments, as discussed
above, were done to characterize the mutant human GR.
Western analysis and hormone binding as discussed above
were performed to ensure character of the constructs,
10 e.g., cell expression of the protein, lack of steroid
specificity for activation or repression of transcription
and base level of gene expression as compared to
constitutive expression.

Example 2915 Transcriptional Activity of the Mutant Receptors in Mammalian Cells

The constitutively active mutant GR construct was
prepared as discussed above. The receptor has no ligand
binding domain and, when expressed in cells, represses
20 transcription of AP-1 driven genes in the absence of dex
or RU486. In vitro testing shows that the constitutively
active GR mutant when transfected constitutively activates
promoters with glucocorticoid responsive elements and
represses AP-1 containing promoters.

25 Construction, Characterization and Analysis of Mutations in the DNA Binding or Transregulatory Domains of GRExample 30Mutagenesis of the DNA Binding or Transregulatory Domains of GR

30 For obtaining transactivation activity without
transrepression activity the following construct was
made. The mutated ligand binding domain is mutated as
described above. Procedure details from Lanz, et al.,
Endocrinology 135:2183-2195 (1994) are hereby incorporated
35 by reference, including drawings. The mutated DNA binding

domain is mutated by changing the serine at position 425 to glycine, the leucine at position 436 to valine and the tyrosine and asparagine at positions 478 and 479 to leucine and glycine.

5 For obtaining transrepression activity without transactivation, the following construct was made. The mutated ligand binding domain is mutated as described above. The mutated transregulatory domain is mutated by changing the alanine at position 458 to threonine, the
10 asparagine and alanine at positions 454 and 458 to aspartic acid and threonine, respectively, and the arginine and aspartic acid at positions 460 and 562 to aspartic and cysteine, respectively.

Example 31

15 Characterization of GR Mutants in the DNA Binding or Transregulatory Domains

To ensure the integrity of the mutation, the plasmids containing the mutant GR were sequenced. Further experiments, as discussed above, were done to characterize the
20 mutant GR constructs. Western analysis and hormone binding as discussed above were performed to ensure character of the constructs, e.g., protein expression in cells and steroid specificity for activation or repression of transcription.

25 Example 32

Transcriptional Activity of the Mutant Receptors in Mammalian Cells

The above mutant GR constructs were prepared. The two different receptor constructs have either a mutated
30 DNA binding domain or a mutated transregulatory domain. When expressed in cells, the transrepression only construct with a DNA binding domain mutation represses transcription of AP-1 and NF κ -B driven genes in the presence of dex or RU486. No activation of transcription was
35 observed. *In vitro* testing shows that the GR mutant when

transfected represses AP-1 and NF κ -B containing promoters and does not activate the glucocorticoid responsive genes.

As for the transactivation only construct with a mutated transregulatory domain, activation of transcription was observed in the presence of various steroids. In the presence of dex or RU486 no transrepression of AP-1 or NF κ -B driven genes was detected. *In vitro* testing shows that the GR mutant when transfected activates glucocorticoid responsive genes in response to ligand stimulation but no repression of AP-1 or NF κ -B genes was observed.

Example 33

Chicken, Rat and Mammalian Progesterone Receptors

Chicken, rat and mammalian progesterone receptors are readily available and function by binding to the same DNA regulatory sequence. Chicken and rat progesterone receptors, however, bind a different spectrum of ligands, possessing affinities different from those interacting with human progesterone receptor. Thus, the chicken and rat progesterone receptor can be used as a transgene regulator in humans. Further, it can be used to screen for specific ligands which activate chicken or rat progesterone receptor but not endogenous human progesterone receptor. An example of a ligand is 5 α -pregnane-3,20-dione (dihydroprogesterone) which binds extremely well to chicken and rat progesterone receptor but does not bind or binds very poorly to human progesterone receptor.

Although the unmodified chicken or rat progesterone receptors are already endowed with a different spectrum of ligand binding affinities from the human or other mammals and can be used in its native form, it is important to try to select additional mutated progesterone receptor to create a more efficacious receptor. The differences in chicken, rat and human progesterone receptors are due to a few amino acid differences. Thus, other mutations could be artificially introduced. These mutations would enhance the receptor differences. Screening receptor mutations

for ligand efficacy produces a variety of receptors in which alterations of affinity occur. The initial screening of progesterone mutants was carried out using intermediate levels of ligands. One mutant had lost
5 progesterone affinity entirely, but bound a synthetic ligand RU486 with nearly wild-type efficiency. RU486 is normally considered an antagonist of progesterone function, but had become an agonist when tested using this specific mutant. Because the ligand is synthetic, it does
10 not represent a compound likely to be found in humans or animals to be treated with gene therapy. Although RU486 works as an agonist in this case, it is not ideal because of its potential side effects as an anti-glucocorticoid. Further, it also binds to the wild-type human progesterone.
15 one. Thus, it has the undesirable side effect of reproductive and endocrine disfunction.

This approach is not limited to the progesterone receptor, since it is believed that all ligand activated transcription factors act through similar mechanisms. One
20 skilled in the art recognizes that similar screening of other members of the steroid superfamily will provide a variety of molecular switches. For example, the compound 1,25-dihydroxy-Vitamin D₃ activates the Vitamin D receptor but the compound 24,25-dihydroxy-Vitamin D does not.
25 Mutants of the Vitamin D receptor can be produced which are transcriptionally activated when bound to 24,25-dihydroxy-Vitamin D, but not by 1,25-Vitamin D₃.

One skilled in the art recognizes that the ligands are designed to be physiologically tolerated, easily
30 cleared, non-toxic and have specific effects upon the transgene system rather than the entire organism.

Example 34

Transgenic Animals

A modified glucocorticoid receptor can be used in the
35 production of transgenic animals. A variety of procedures are known for making transgenic animals, including that

described in Leder and Stewart, U.S. Patent No. 4,736,866 issued April 12, 1988, and Palmiter and Bannister, *Annual Review of Genetics*, 20:465-499. For example, the mutated glucocorticoid receptors described above can be combined
5 with the nucleic acid cassette containing the recombinant gene to be expressed. For example, lactoferrin can be placed under the control of a basal promoter, such as thymidine kinase promoter with adjacent glucocorticoid responsive elements. This vector is introduced into the
10 animal germ lines, along with the vector constitutively expressing the mutant glucocorticoid receptor. The two vectors can also be combined into one vector. The expression of the recombinant gene in the transgenic animal is turned on or off by administering a pharmacological dose
15 of RU 38486 to the transgenic animal. This hormone serves to specifically activate transcription of the transgene. The dose can be adjusted to regulate the level of expression. One skilled in the art will readily recognize that this protocol can be used for a variety of genes and,
20 thus, it is useful in the regulation of temporal expression of any given gene product in transgenic animals.

Location of Transregulatory Domains at the C-Terminal

Example 35

Chimeric Fusion Protein with Various C-terminal Deletion

25 To construct GLVP chimeras with various C-terminal deletions of the human progesterone receptor ligand binding domain, the HindIII to BamHI fragment containing these various deletions in pRSV-hPR plasmids (Xu et al. (1996) (unpublished)) was gel purified with QIAEX II gel
30 extraction kit (Qiagen). The purified fragments were subcloned into HindIII and BamHI sites of pRSV-GLVP (Wang et al., *Proc. Natl. Acad. Sci.* 91:8180-8184 (1994)) replacing the amino acid region 610 to 891 of the GLVP.

Example 36GLVP_C Chimeras with VP16 Activation at the C-terminus

Two-step clonings were used to move VP16 activation to the C-terminus of the chimeric fusion protein. First, the hPR -LBD region (from amino acid 800 to various C-terminus) was amplified using 5' primer (5'-TATGCCTTACCA TGTGGC-3' (Seq. ID No. 7)) with a different 3' primer as a pair and digested with HindIII to SalI to prepare the fragment for ligation. For a different position of amino acid truncation, the 3' primers incorporating the SalI site are: P3S-879: 5'-TTGGTCGACAAGATCATGCATTATC-3' (Seq. ID No. 9); P3S-891: 5'-TTGGTCGACCCGACGTACAGATGAAGTTG-3' (Seq. ID No. 10) and P3S-914: 5'-TTGGTCGACCCAGCAATAACTTCA GACATC-3'. The DNA fragment containing the VP16 activation domain (amino acid 411-490) was isolated from pMSV-VP16-Δ3'-β58N' with SalI and BamHI.

The digested PCR fragment and VP16 activation were ligated together into the HindIII and BamHI sites of expression vector pCEP4 (Invitrogen). The ligated vector pCEP4-PV (LBD 810-879 and VP16), -C3 (LBD 810-891 and VP16), -C2 (LBD 810-914 and VP16), respectively, now contain C-terminal fragments of hPR-LBD from the HindIII site (amino 810) to various truncations of LBD fused 3' to VP16 activation domain with BamHI after the termination codon of VP16. The HindIII-BamHI fragment from pGL (in pAB vector) was then replaced with PV, C3, and C2 fragment, respectively, to yield pGL₈₇₉VP_C, pGL₈₉₁VP_C, and pGL₉₁₄VP_C. These chimeric fusion proteins were then subcloned into Acc65I and BamHI sites of pCEP4 expression and were named as pCEP4-GL₈₇₉VP_C, pCEP4-GL₈₉₁VP_C, pCEP4-GL₉₁₄VP_C (Fig. 17).

The regulator with a C-terminally located VP16 is more potent than its N-terminal counterpart (Fig. 18). In addition, extension of the C-terminal LBD from amino acid 879 to amino acid 914 further increased transactivational activity of the regulator in this C-terminally located VP16 chimera. Thus, extension of the LBD to amino acid

914 further enhances the RU486-dependent transactivation, irrespective of whether VP16 is located in the N- or C-terminus, suggesting the existence of a weak dimerization and activation function between amino acid 879 and 914 of the PR-LBD. By transferring the VP16 activation domain from the N-terminus to the C-terminus, a much more potent transactivator GL₉₁₄VP_C was generated.

The modified GL₉₁₄VP_C is not only more potent but also activates the reporter gene at a lower concentration of ligand as compared to GL₉₁₄VP where VP16 is located at the N-terminus. GL₉₁₄VP activity occurred at an RU486 concentration of 0.1 nM and reached a maximal level at 1 nM. In contrast, GL₉₁₄VP_C increased reporter gene expression at an RU486 concentration 10 fold lower (0.01 nM) than that of GL₉₁₄VP. This newly discovered character of GL₉₁₄VP_C is important for its use in inducible target gene expression, since it would allow use of a concentration which has no anti-progesterone or anti-glucocorticoid activity. This represents a significant advantage when the inducible system is applied in *in vivo* situations, as exemplified by transgenic mice and gene therapy.

Example 37

Inducible Repressor Containing the Kid-1 KRAB domain

The Kid-1 gene containing the KRAB domain (aa. 1-70) was amplified with 2 sets of primers for insertion into the N- or C-terminus of GL₉₁₄, respectively. For the KRAB domain to be inserted at the N-terminus of the fusion protein, the Kid-1 cDNA was amplified with the set of primers as follows: Kid3: 5'-CGACAGATCTGGCTCCTGAGCAAAGA GAA-3' (Seq. ID No. 11), Kid4: 5'-CCAGGGATCCTCTCCTTGCTG CAA-3' (Seq. ID No. 12). The PCR products were digested with BglII and BamHI and subcloned into pRSV-GL₈₉₁ to create pRSV-KRABGL₈₉₁. The KpnI-SalI fragment of KRABGL₈₉₁ was then purified and subcloned into KpnI-SalI sites in pRSV-GL₉₁₄VP to create pRSV-KRABGL₉₁₄. The entire KRABGL₉₁₄ fragment

(KpnI-BamHI) was then inserted into the KpnI and BamHI digested pCEP4 generating pCEP4-KRABGL₉₁₄ (Fig. 19).

For C-terminally located KRAB domain, the Kid-1 gene was amplified with the following set of primers: Kid1: 5'-TCTAGTCGACGATGGCTCCTGAGCAAAGAGAAG-3' (Seq. ID No. 13), Kid2: 5'-CCAGGGATCCTATCCTTGCTGCAACAG (Seq. ID No. 14). The primer Kid2 also contains a termination codon (TAG) after aa. 70. The PCR products were digested with Sall and BamHI and purified using QIAEX II gel extraction kit (Qiagen). The HindIII and Sall fragment (317 bp) from pBS-GL₉₁₄VP_C, was isolated as is the vector fragment of pCEP4-GL₉₁₄VP_C digested with HindIII and BamHI. These three piece fragments were ligated to create pCEP4-GL₉₁₄KRAB.

The chimeric regulator GL₉₁₄KRAB, with the KRAB repression domain inserted in the C-terminus, strongly repressed expression (6-8 fold) of both reporters in an RU486-dependent manner. However, the N-terminally located KRAB repression domain (KRABGL₉₁₄) did not repress target gene expression in the presence of RU486 to the degree of that achieved with KRAB located in the C-terminus (GL₉₁₄KRAB).

Example 38

Transient Transfection, CAT Assay, hGH assay and Western Blot

HeLa and CV1 cells were transfected with the described amount of DNA using the polybrene mediated Ca₂PO₄ precipitation method and CAT assay was performed and quantified as described above (Wang et al., *Proc. Natl. Acad. Sci.* 91:8180-8184 (1994)). HepG2 cells (10⁶) were grown in DMEM with 10% fetal bovine serum and 1X Penicillin-Streptomycin-Glutamine (Gibco BRL) and transfected with polybrene mediated Ca₂PO₄ precipitation method. Aliquots of the cell culture media were taken at different time intervals and hGH production was measured using the hGH clinical assay kit (Nichols Institute) according to

the manufacture's instruction. For Western blot analysis, protein extracts (20 µg) were prepared from transiently transfected HeLa cells, separated on SDS polyacrylamide gel and trans-blotted onto nylon membrane as described
5 above. The blot was probed with anti-GAL4-DBD (aa. 1-147) monoclonal antibody (Clontech) and developed with an ECL kit (Amersham).

These analyses confirmed that the two regulator proteins are expressed at a similar level. Together,
10 these results suggest that through modification of the PR-LBD within the chimeric regulator we could further improve its response to a ligand by at least one order of magnitude.

Example 39

15 Stable Cell Line Generation and Neurite Outgrowth Assay

To demonstrate the use of the inducible system in a biological situation, a regulatable expression model for nerve growth factor (NGF) was designed. NGF has been shown to stimulate neurite (axon) outgrowth of PC12 cells
20 (from rat adrenal pheochromocytoma) when added to the cell culture media (Greene et al., *Proc. Natl. Acad. Sci.* 73:2424-2428 (1976)).

Rat FR cells, derived from rat fetal skin cells (American Type Culture Collection, CRL 1213) were trans-
25 fected with pCEP4-GLVP₉₁₄VP_C by the ₂Ca₄PO method as described previously (Wang et al., *Proc. Natl. Acad. Sci.* 91:8180-8184 (1994)). Cells were grown in DMEM with 10% fetal bovine serum and selected with 50 µg/ml hygromycin-B (Boehringer Mannheim). After 2-3 weeks colonies were
30 picked and subsequently expanded. Each clone was then transiently transfected with 2 µg of the p17X4-TATA-CAT plasmid utilizing Lipofectin (GIBCO-BRL). Twenty-four hours later, the cells were treated with either RU486 (10⁻⁶M) or 80% ethanol vehicle. Cells were harvested 48 hours
35 later and CAT activity was measured using 50 µg of cell extracts. Clones showing RU486 inducible CAT activity

were subsequently transfected with the vector p17X4-TATA-rNGF(Neo).

Stable cells containing both genes were selected with hygromycin (50 µg/ml) and G418 (100 µg/ml) for 2-3 weeks and subsequently expanded. Each colony was then seeded into a 10 cm culture dish and treated with 10^{-8} M RU486 or vehicle control (80% ethanol). After 48 hours, the conditioned media was collected and frozen. Subsequently, the conditioned media was thawed and diluted two-fold in DMEM with 10% horse serum and 5% fetal bovine serum. The diluted conditioned media was then placed on PC12 cells, with new diluted conditioned media added every two days. After 5-7 days, PC12 cells were observed for neurite outgrowth.

When conditioned media (from C4FRNGF cells treated with RU486) was added to PC12 cells, strong neurite outgrowth from PC12 cells was observed after 48 hrs of incubation. Little if any neurite outgrowth was observed in PC12 cells incubated with the conditioned media that was collected from stable cells treated with vehicle only (85% ethanol). These results demonstrate that the inducible system can be used to control various biological phenomenon.

Mutated Glucocorticoid Receptors as Gene Switch

In addition to the above methods, the mutated glucocorticoid receptors can be used as gene switches as described in U.S. Serial No. 07/939,246, by Vegeto et al., filed September 2, 1992, entitled "Mutated Steroid Hormone Receptors, Methods for Their Use and Molecular Switch for Gene Therapy," the whole of which (including drawings) is hereby incorporated by reference. The above constructs of the present invention can be used to express a co-transfected target therapeutic gene using a glucocorticoid response element ("GRE") containing promoter. The GRE promoter will drive, activate or transactivate expression of the therapeutic gene upon activation of the ligand

binding domain of the constructs of the present invention. The therapeutic protein can be a secreted protein, e.g., an anti-inflammatory cytokine. Such methods allow more global effect on the transfected tissue.

5 One skilled in the art would readily appreciate that the present invention is well adapted to carry out the objects and obtain the ends and advantages mentioned, as well as those inherent therein. The mutated steroid receptors along with the methods, procedures, treatments, 10 molecules, specific compounds described herein are presently representative of preferred embodiments are exemplary and are not intended as limitations on the scope of the invention. Changes therein and other uses will occur to those skilled in the art which are encompassed 15 within the spirit of the invention are defined by the scope of the claims.

It will be readily apparent to one skilled in the art that varying substitutions and modifications may be made to the invention disclosed herein without departing from 20 the scope and spirit of the invention.

All patents and publications mentioned in the specification are indicative of the levels of those skilled in the art to which the invention pertains. All patents and publications are herein incorporated by reference to the 25 same extent as if each individual publication was specifically and individually indicated to be incorporated by reference.

Other embodiments are within the following claims:

Claims

1. A modified glucocorticoid receptor protein capable of binding a non-natural ligand, comprising a fusion protein, wherein said fusion protein comprises:
5 glucocorticoid receptor region, wherein said region comprises a DNA binding domain and one or more trans-regulatory domains, wherein each said transregulatory domain is capable of transactivating or transrepressing gene expression; and a mutated progesterone receptor
10 ligand binding region, wherein said mutated progesterone receptor ligand binding region is capable of binding a non-natural ligand.
2. The modified glucocorticoid receptor of claim 1, wherein said mutated progesterone receptor ligand binding
15 region is mutated by deletion of about 16 to 42 carboxyl terminal amino acids of a progesterone receptor ligand binding domain.
3. The modified glucocorticoid receptor protein of claim 1, wherein said mutated progesterone receptor ligand
20 binding region consists essentially of amino acids 640 through 891 of a progesterone receptor ligand binding domain.
4. The modified glucocorticoid receptor protein of claim 1, wherein said mutated progesterone receptor ligand
25 binding region consists essentially of amino acids 640 through 917 of a progesterone receptor ligand binding domain.
5. The modified glucocorticoid receptor protein of claim 1, wherein said mutated progesterone receptor ligand
30 binding region consists essentially of amino acids 640 through 920 of a progesterone receptor ligand binding domain.

6. A modified glucocorticoid receptor protein comprising a ligand binding domain without ligand binding activity, a DNA binding domain and transregulatory domains, wherein said transregulatory domains are capable
5 of constitutively transactivating or transrepressing gene expression without said ligand binding activity.

7. A modified glucocorticoid receptor protein capable of binding a non-natural ligand, comprising: a glucocorticoid receptor region, wherein said region com-
10 prises a DNA binding domain and a mutated transregulatory domain, wherein said transregulatory domain is capable of transactivating but not transrepressing gene expression; and a mutated ligand binding domain.

8. A modified glucocorticoid receptor protein
15 capable of binding a non-natural ligand, comprising: a glucocorticoid receptor region, wherein said region comprises a mutated DNA binding domain and transregulatory domains, wherein said transregulatory domains are capable of transrepressing but not transactivating gene expres-
20 sion; and a mutated ligand binding domain.

9. A modified glucocorticoid receptor protein capable of binding a non-natural ligand, wherein said protein comprises a DNA binding domain, transregulatory domains and a mutated ligand binding domain, wherein said
25 mutated ligand binding domain is mutated by deletion of about 2-5 carboxyl terminal amino acids from the ligand binding domain and capable of binding a non-natural ligand.

10. The modified glucocorticoid receptor protein of
30 claim 9, wherein said protein is mutated by deleting amino acids 762 and 763 of the ligand binding domain and changing amino acid at position 752 to alanine and amino acid at position 753 to alanine.

11. A nucleic acid sequence encoding a modified glucocorticoid receptor protein of 1, 6, 7, 8 or 9.

12. A vector containing a nucleic acid sequence encoding for a modified glucocorticoid receptor protein of
5 1, 6, 7, 8 or 9, wherein said vector is capable of expressing said modified glucocorticoid receptor protein.

13. A cell transfected with a vector of claim 12.

14. A cell transformed with a vector of claim 12.

15 15. A method of using a modified glucocorticoid receptor protein comprising the steps of transforming a
10 cell with a vector of claim 12, wherein said transformed cells express said modified glucocorticoid receptor protein and said modified glucocorticoid receptor protein is capable of regulating the expression of glucocorticoid
15 responsive genes by a non-natural ligand.

16. The method of claim 15, wherein said non-natural ligand is RU486.

17. The method of claim 15, wherein said regulation is transactivation of glucocorticoid responsive genes.

20 18. The method of claim 15, wherein said regulation is transrepression of $\text{NF-}\kappa\text{-B}$ and AP-1 regulated genes.

19. The method of claim 15, wherein said transformed cell is selected from the group consisting of a muscle cell, lung cell or a synovial cell.

25 20. A method of treating arthritis comprising the steps of transforming cells associated with the joints *in situ* with a vector of claim 12 encoding a mutated glucocorticoid receptor protein, wherein said transformed

cells express said mutated glucocorticoid receptor protein and said mutated glucocorticoid receptor protein is capable of regulating the expression of glucocorticoid responsive genes by a non-natural ligand.

5 21. The method of claim 20, wherein said non-natural ligand is RU486.

 22. The method of claim 20, wherein said regulation is transactivation of glucocorticoid responsive genes.

10 23. The method of claim 20, wherein said regulation is transrepression of NF κ -B and AP-1 regulated genes.

 24. A method of treating asthma comprising the steps of transforming lung cells *in situ* with a vector of claim 12 encoding a modified glucocorticoid receptor protein, wherein said modified glucocorticoid receptor protein
15 expressed in said transformed cell is capable of regulating expression of glucocorticoid responsive genes by a non-natural ligand.

 25. The method of claim 24, wherein said non-natural ligand is RU486.

20 26. The method of claim 24, wherein said regulation is transactivation of glucocorticoid responsive genes.

 27. The method of claim 24, wherein said regulation is transrepression of NF κ -B and AP-1 regulated genes.

25 28. A method of making a transformed cell *in situ* comprising the step of contacting said cell with a vector of claim 12 for sufficient time to transform said cell, wherein said transformed cell expresses a modified glucocorticoid receptor protein encoded by said vector.

100

29. A transgenic animal whose cells contain a vector of claim 12.

30. A plasmid designated as pGR0403R.

31. A cell transformed with a plasmid of claim 30.

5 32. The modified glucocorticoid receptor protein of claim 1, wherein said mutated progesterone ligand binding region consists essentially of amino acids 640 through 914 of a progesterone receptor ligand binding domain.

10 33. The modified glucocorticoid receptor protein of claim 1, wherein said transregulatory domain is located in the N-terminal region of said mutated progesterone ligand binding domain.

15 34. The modified glucocorticoid receptor protein of claim 1, wherein said transregulatory domain is located in the C-terminal region of said mutated progesterone ligand binding domain.

35. The modified glucocorticoid receptor protein of claim 7, wherein said modified glucocorticoid receptor protein activates target gene expression.

20 36. The modified glucocorticoid receptor protein of claim 1, wherein said DNA binding domain is a GAL4 DNA binding domain.

25 37. The modified glucocorticoid receptor protein of claim 35, wherein said target gene encodes nerve growth factor.

38. The modified glucocorticoid receptor protein of claim 1, wherein said transregulatory domain comprises a Krüppel-associated box-A (KRAB) transrepressing domain.

39. The modified glucocorticoid receptor protein of claim 1, wherein said mutated progesterone receptor ligand binding region is capable of responding to RU486 at a concentration as low as 0.01 nM.

- 5 40. A modified steroid hormone receptor protein, wherein said receptor responds to a conventional antagonist of the wild-type steroid hormone receptor protein counterpart with an agonistic response.

(54) Title: MODIFIED GLUCOCORTICOID RECEPTORS, GLUCOCORTICOID RECEPTORS/PROGESTERONE RECEPTORS HYBRIDS

(57) Abstract

The present invention provides modified proteins of steroid hormone receptors. These mutated proteins are useful as gene medicines. In particular, these mutated proteins are useful for regulating expression of genes in gene therapy. In addition, the present invention provides plasmids encoding for the desired mutated steroid hormone receptor proteins, as well as cells transfected with those plasmids.

INTERNATIONAL SEARCH REPORT

national application No.

PCT/US 97/ 19607

Box I Observations where certain claims were found unsearchable (Continuation of item 1 of first sheet)

This International Search Report has not been established in respect of certain claims under Article 17(2)(a) for the following reasons:

1. ☒ Claims Nos.:
because they relate to subject matter not required to be searched by this Authority, namely:
Remark: Although claim(s) 20-28
is(are) directed to a method of treatment of the human/animal
body, the search has been carried out and based on the alleged
effects of the compound/composition.
2. ☐ Claims Nos.:
because they relate to parts of the International Application that do not comply with the prescribed requirements to such
an extent that no meaningful International Search can be carried out, specifically:
3. ☐ Claims Nos.:
because they are dependent claims and are not drafted in accordance with the second and third sentences of Rule 6.4(a).

Box II Observations where unity of invention is lacking (Continuation of item 2 of first sheet)

This International Searching Authority found multiple inventions in this international application, as follows:

SEE ADDITIONAL SHEET

1. ☒ As all required additional search fees were timely paid by the applicant, this International Search Report covers all
searchable claims.
2. ☐ As all searchable claims could be searched without effort justifying an additional fee, this Authority did not invite payment
of any additional fee.
3. ☐ As only some of the required additional search fees were timely paid by the applicant, this International Search Report
covers only those claims for which fees were paid, specifically claims Nos.:
4. ☐ No required additional search fees were timely paid by the applicant. Consequently, this International Search Report is
restricted to the invention first mentioned in the claims; it is covered by claims Nos.:

Remark on Protest

- ☐ The additional search fees were accompanied by the applicant's protest.
- ☒ No protest accompanied the payment of additional search fees.

International Application No. PCT/US 97/19607

FURTHER INFORMATION CONTINUED FROM PCT/SA/ 210

This International Searching Authority found multiple (groups of) inventions in this international application, as follows:

1. Claims: 1-5,32-34,36,38,39 completely, 11-29 partially

A fusion protein consisting of a DNA binding region and transregulatory domain of a glucocorticoid receptor, and a mutated ligand binding domain of a progesterone receptor. Expression of said fusion protein, uses as pharmaceutical, transgenic animal encoding said protein.

2. Claims: 6,30,31 completely, 11-29 partially

A glucocorticoid receptor without ligand binding domain . Expression of said protein, uses as pharmaceutical, transgenic animal encoding said protein.

3. Claims: 7-10,35,37 completely, 11-29 partially

A glucocorticoid receptor having a mutated ligand binding domain . Expression of said mutant, uses as pharmaceutical, transgenic animal encoding said protein.

4. Claim : 40

A modified steroid hormone receptor activated by an antagonist of the non modified steroid hormone receptor.
